Printed by Toppan Printing Company Limited, Tokyo, Japan

PREFACE

Microbiology continues to become more and more obviously a basic discipline, and one which underlies much of current biological thinking. Modern genetics and molecular biology, for example, are microbial genetics and molecular microbiology in present substance, and provide a foundation upon which concepts in these areas are developing. In this rapidly expanding role microbiology tends to become more and more complex, necessitating frequent revision of a book such as this.

The present volume has been extensively revised over its immediate predecessor. with changes and additions ranging from complete rewriting at the chapter level, through reorganization of a considerable portion of the subject matter, to new and completely rewritten sections. The chapter on medical mycology is completely new. with new illustrations. With more or less general acceptance of viral characteristics, largely structural in nature, a provisional classification of these agents has evolved, together with a number of contracted, yet still familiar names, which promises the evolution of an orderly relationship in this area of microbiology. While it is hardly practical at this time to accept the detailed differentiation and nomenclature which has been proposed by some, it is now possible to relate these viral agents to one another on a basis other than the doubtful one of host or tissue specificity. The viruses have, therefore, been reorganized, both in terms of their taxonomy and in the order of their consideration. The latter is reflected in the transposition of the discussions of a number of them, such as measles and rabies viruses, and in the reorganization of the arboviruses. It is possible, too, that the application of the methods of numerical taxonomy, discussed in a new section, to the bacteria may lead to a more realistic appraisal of the interrelationships of these, and possibly eventually other, microorganisms.

The spread of cholera within the past few vears, consistent with the initial stages of a new pandemic, has stimulated a great deal of research on this disease, leading to the elucidation of certain of the mechanisms of its pathogenesis and pathophysiology and to a broader concept of the causative organism as a group of biotypes. Such accumulation of new information has required a large amount of rewriting of the chapter devoted to these microorganisms. Presently available knowledge of the function of ribosomes and the functional types of RNA has led to the complete rewriting of relevant sections, as has the eludication of bacterial nuclear structure and function, including such peripheral matters as the episomal aspects of drug resistance among the gram-negative enteric bacilli. Elegant studies on the pathogenesis of bacillary dysentery have led to an understanding of the pathogenesis of these infections and certain genetic aspects of microbial virulence.

Similarly, very great progress has been made in the study of antibody as immunoglobulins, though it is as yet too soon to relate with certainty some of these, such as IgA secretory immunoglobulin, to effective immunity. The relation of ontogeny to the immune response and the role of the thymus as a source of antibody-forming cells are now beginning to emerge to form the basis of new sections. The material on the measles and rubella viruses is entirely new, and the diverse etiology of the common cold has become increasingly evident, lead-

PREFACE

ing to an entirely rewritten and expanded section. The section on food poisoning and foodborne infection has been consolidated from its dispersal among the various causative microorganisms and appears as a completely rewritten and considerably expanded section, including consideration of control of such disease.

The inclusion of bibliographies at the end of each chapter, initiated in the immediately preceding edition, has been continued, with various research papers, reviews, and monographs being given in full, including titles in the original language. Inevitably any such compilation is individualistic in nature and undoubtedly omits publications which should have been included. The author has reason to believe, however, that such bibliographies, current and updated, have been useful to their original purpose -i.e., to provide the student with an entrée to the rich and rewarding literature of microbiology-and hopes that they will continue to fulfill this intended function.

Dr. J. W. Moulder has been good enough

to continue his complete responsibility for consideration of microbial metabolism, and Dr. R. M. Lewert has prepared the revision of the chapter on medical parasitology. The author is especially indebted to Dr. J. W. Rippon for his extensive work, including the preparation of very many original illustrations and the complete rewriting of the chapter on medical mycology. The author is grateful also to many other co-workers and friends for advice, criticism, and access to unpublished material, especially Dr. R. S. Benham and Miss Isabelle Havens, Dr. E. H. LaBrec, and Dr. S. B. Formal. Mrs. Barbara Hilbrant has provided invaluable secretarial assistance. And to more than any other one individual, the author is indebted to his wife, not only for her forebearance during some thirty years of association with this book, but also for her assumption of complete responsibility for all bibliographic matters.

WILLIAM BURROWS

Chapter One

THE HISTORICAL DEVELOPMENT OF MICROBIOLOGY

The term microbiology is commonly used in a more narrow sense than its etymology suggests. It does not refer to the broader subject of small or minute living organisms, but rather has come to be restricted to those microorganisms that are directly or closely related to human activity and welfare.

The microorganisms as a group resist precise taxonomic limitation in that they spread over both the plant and animal kingdoms, from the fungi of obvious plant affinities to the unicellular and small multicellular animals. In this scheme of things the true bacteria, or Eubacteriales, occupy a position between the two kingdoms and in a real sense constitute a link between them. The viruses, distinguished by their obligate parasitic relationship to the cells of their hosts, are perhaps to be regarded as an offshoot of the bacteria, and are of unique interest in that many of them seem to occupy a borderline position between the living and the nonliving.

The consequences of the varied activities of many of the microorganisms have been familiar to man from prehistoric times. Decomposition of organic matter and especially spoilage of foods, acetic and lactic acid fermentations and alcoholic fermentation, degradation of proteins with the production of new and desirable flavors in certain foods, and the occurrence of infectious disease are obvious examples of familiar phenomena now known to be of microbial etiology.

The existence of these etiological agents may be inferred from such consequences of their activity, and their living nature from the ability to reproduce the observed effects indefinitely in series by, for example, the transfer of a small portion of a fermenting mixture to fresh, unfermented substrate. It is probable that such inferences were made early, for many statements may be found in both ancient and later writings which may be interpreted as supporting this idea. Thus Lucretius writes of "the seeds of disease" in his *De Rerum Natura*, Fracastorius of Verona in 1546 suggested a contagium vivum as a cause of disease, and von Plenciz accounted for the specificity of disease on the basis of a microbial etiology in 1762.

Nevertheless, appreciation of the abstract concepts commonplace in modern science is a relatively recent development, and even yet these are often accepted by man in general more on faith than on intellectual understanding. So an essential feature of the beginnings of a scientific microbiology was the demonstration of these agents in such a way that they were more or less directly evident to the senses. This was accomplished by the development of optical systems of sufficient precision to allow them to be seen.

MICROSCOPY

The name of Antony van Leeuwenhoek is inseparably associated with the early development of microscopy. Van Leeuwenhoek lived in the latter part of the seventeenth and early part of the eighteenth centuries (1632–1723) in Delft. He held a political sinecure and was able to devote the greater part of his time to the hobby of lens grinding. He not only made the best lenses available to that time, but used them in examination of a wide variety of materials that interested him. It was characteristic that he first observed bacteria in an attempt to discern in visual

terms the nature of the taste of pepper. There is no doubt that he actually observed these microorganisms for he made recognizable drawings of them that were reproduced in his report⁹ of his observations to the Royal Society. In the relevant portion of this report he wrote:

Having several times endeavoured to discover the cause of the pungency of pepper upon our tongue, and the rather because it hath been found, that though pepper had layn a whole year in vinegar, yet it retained still its pungency; I did put about 1/3 of an ounce of whole pepper in water, placing it in my study, with this design, that the pepper thereby being rendered soft, I might be enabled the better to observe what I had proposed to myself. This pepper having lain about three weeks in the water, to which I had added some snow water, the other water being in great part exhaled. I looked upon it the 24th of April, 1676 and discern'd in it, to my great wonder, an incredible number of little animals, of divers kinds. . . . The 4th sort of creatures, which moved through the three former sorts, were incredibly small and so small in my eye, that I judge, that if 100 of them lay one by another, they would not equal the length of a grain of coarse sand; and according to this estimate, ten hundred thousand of them could not equal the dimensions of a grain of such sand.

A few of the hundreds of microscopes he constructed are still available, and it is evident that the maximum magnification he reached was approximately 300 diameters. This is not sufficient to allow observation

unquam sanguinem emittat. Nec tan sunt puri, quin, ubi eos per specult tuerer, viderim crescentem inter de

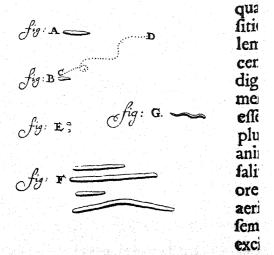

Figure 1. The first pictorial representation of bacteria. (Reproduced from Arcana Naturae delecta ab Antonio van Leeuwenhoek. Delphis Batavorum apud Henricum Crooneveld. 1695.)

of objects as small as bacteria by transmitted light. While van Leeuwenhoek was never willing to reveal his method of illumination, it seems probable that he used reflected light as it is used in the modern darkfield microscope.

The direct demonstration of living organisms of such small dimensions was a notable achievement, but any relation of such forms to natural phenomena such as fermentation or infectious disease either escaped van Leeuwenhoek or was of no interest to him. Their possible relation to gross phenomena was apparent to at least some, and possibly many, scientific men of his day. For instance, in a comment on a report of an epidemic disease of cattle published five years later, his contemporary, Slare, wrote:¹⁰

I wish Mr. Leeuwenhoek had been present at some of the dissections of these infected Animals, I am perswaded he would have discovered some strange Insect or other in them.

But systematic study was delayed for many years, and it was nearly a century later. in 1786, that the Danish zoologist, O. F. Müller, studied the bacteria and succeeded in discovering many details of their structure. He left drawings so accurate that the bacteria he showed can be identified today as belonging to one or another of the chief divisions. Somewhat later, in 1838, Ehrenberg published his work Infusionstierchen in which he put the study of these microorganisms on a systematic basis and was able to establish a number of groups by clearly recognizing fundamental morphological distinctions, such as those differentiating the spirochetes from certain of the protozoa with which others had grouped them. Some of the names he used, such as "bacterium" and "spirillum," are still current in bacteriological nomenclature though with somewhat changed significance. In the next two or three decades considerable knowledge was amassed by such men as Dujardin, Perty, Nägeli, Cohn, and others. It is of more than passing interest that Cohn was Koch's professor.

The perfection of the modern compound microscope, with achromatic and then with apochromatic and fluorite objective lenses, markedly facilitated the study of the morphology of microorganisms, and at least certain of the gross internal structures of the bacterial cell as well as some of the larger viruses could be observed. This made possible accurate differentiation of microorganisms on a morphological basis and provided the basic criteria for characterization of the larger forms, the fungi, protozoa, and metazoa. The introduction of phase miscroscopy in the 1940's further facilitated certain aspects of microscopy, especially the observation of microorganisms in the living state, by accentuation of slight differences in the refractive indices of intracellular elements.

Optical microscopy is, nevertheless, limited by the resolution that may be obtained with visible light to a working limit in magnification of 1000 to 2000 diameters and resolution of objects as small as 0.2μ . It was obvious that such resolution limits are inadequate for study of much of the intracellular structure of bacteria and, further, that living organisms beyond the limits of optical resolution existed. The darkfield microscope, although facilitating the observation of tenuous microorganisms such as the spirochetes and structures such as flagella, shows minute objects only as points of light against a dark background without increasing resolution. The use of ultraviolet light in substantially the conventional compound microscope equipped with quartz lenses resulted in some small increase in resolving power in the 1920's, but the fundamental limitation of the size of the object in relation to the wave length of the light used still remained.

Within the next decade or two the electron microscope was developed in practical usable form. It constituted an important advance in microscopy in that an object or structure casting a "shadow" in the electron beam may be resolved, and working magnifications of 30,000 diameters with excellent resolution were obtained. Thus it became possible to photograph microorganisms beyond the limits of optical resolution and to demonstrate directly morphological characteristics down to and including the orientation of the macromolecules that represent the complete unit of certain of these agents.

SPONTANEOUS GENERATION

For many years it was generally believed that living organisms could arise *de novo* and fully formed from decomposing organic matter. The development of snakes from

horse hairs standing in stagnant water and the appearance of mice in decomposing fodder are familiar examples that, in fact, persist in some areas to the present time. The fallacies in such beliefs were suspected by some, and in the seventeenth century a number of individuals carried out experiments designed to show whether living organisms had their origin only in other living organisms (biogenesis), or appeared spontaneously in decomposing organic matter (abiogenesis).

The poet-physician Redi carried out experiments in the middle of the seventeenth century that showed, contrary to popular belief, that maggots were not formed spontaneously in decomposing meat but were fly larvae hatched from eggs deposited in the meat. Spallanzani, an Italian monk, showed further that putrescible meat infusions did not spoil when properly heated and did not contain living organisms even though kept over long periods. Needham, an Irish priest, took issue with Spallanzani on the basis of similar experiments in which spoilage took place and living organisms appeared in spite of previous heating. A second series of elaborate experiments by Spallanzani corroborated his earlier findings and indicated the fallacies in Needham's experiments. It was evident that the source of microorganisms was air, and this was convincingly demonstrated by many other workers, including Schulze, Schwann, Schröder and von Dusch, and Tyndall.

The whole question seemed settled conclusively in favor of biogenesis when it was raised again in the middle of the nineteenth century by the work of the eminent French chemist Pouchet. He made the same kind of technical errors as some of his predecessors had, so that his evidence supported the hypothesis of spontaneous generation of life. It was at this point that Pasteur entered the renewed controversy through his early studies on fermentation, and he was able to show beyond any reasonable doubt that the source of microorganisms was air by demonstration of the varying numbers of microorganisms in air from various sources, and by ingenious experiments in which the heated material had free access to air through tortuous passages that allowed bacterialaden dust to settle before the air reached the putrescible test materials.

The validity of biogenesis has not since

been seriously questioned. While biogenesis may seem self-evident today, it was a matter of fundamental importance to biology that it be fully established. Had this not been done the specific microbic etiology of fermentation, decay, infectious disease, and similar phenomena could not have been established. At the same time present concepts of evolution, and biochemical evidence in particular, seem to point inevitably toward an original emergence of life from the non-living (Chap. Three).¹¹

FERMENTATION AND BIOCHEMICAL PHYSIOLOGY

By the middle of the nineteenth century the general nature of organic material was becoming relatively clear, but the natural decomposition of these substances was not, in that the part played by microorganisms in the processes of putrefaction, decay, and fermentation was not known. This is something of an inconsistency in that in some of the earlier studies on spontaneous generation, the decomposition of meat infusions was taken as evidence of the presence of living organisms and, since the organisms were not found in the absence of decomposition, a causal relation was suggested.

The plant-like nature of yeast had been shown by Caignard-Latour and by Schwann, but the chemists of the day, Liebig, Berzelius, and Wöhler, regarded the presence of yeast cells in a fermenting mixture as no more than incidental to the decomposition which was considered to have a purely inanimate basis.

Pasteur (1822-1895), originally trained as a chemist, had done his early work on stereoisomerism. The formation of optically active amyl alcohol during the course of the lactic acid fermentation led him to the study of the processes of fermentation. Having first established the validity of biogenesis, it was not difficult to prove that fermentations resulted from the physiological activity of living, growing microorganisms. It is now clear, of course, that while the living organism is an indispensable adjunct to fermentation, catalysis of the process is a function of the enzymes formed by the living cell and may be brought about by cell-free preparations.

The specificity of fermentations, the fact that different kinds of fermentations characterized by differences in predominant end products result from the activities of different kinds of microorganisms, grew out of this work and was the beginning of the establishment of the important principle of specific microbic etiology. Pasteur applied this in his work on the "diseases" of beer and wine and showed these were none other than secondary fermentations brought about by extraneous microorganisms that gave undesirable end products. He controlled the fermentative process by gentle heating to destroy undesirable microorganisms, followed by inoculation of the fermentable mixture with microorganisms that brought about the desired fermentation. This method of gentle heating, now also widely applied to destroy pathogenic microorganisms that may be present in milk, has been named "pasteurization" in his honor.

Study of the mechanisms of fermentation was tremendously stimulated by the commercial value of end products such as ethanol, lactic and acetic acids, glycerol, butanol, and acetone on the one hand, and on the other by the obvious similarities in the metabolism of carbohydrate by many microorganisms and by higher animals, including man. The former consideration led to the establishing of a new industry concerned with the large scale production of organic solvents and subsequently other microbial products, especially vitamins and antibiotics.

The chemistry of microorganisms, necessitated by their morphological simplicity and physiological complexity, grew side by side with the chemical approach to mammalian physiology, eventually fusing into presentday biochemistry. As indicated above, the initial common ground was carbohydrate metabolism and the respiratory processes, astonishingly closely similar in such widely dissimilar organisms. Thus, the phenomenon of anaerobic respiration, first observed by Pasteur in fermenting mixtures and received with incredulity at the time, is now commonplace in biochemical physiology. More detailed study showed that the catalysis of the processes of respiration is substantially the same also, and characterization of the iron porphyrin and flavoprotein enzymes, for example, was markedly facilitated by their availability in microorganisms. Many of the vitamins required by mammals, especially those of the B group, are also required by microorganisms, and apparently function in the same manner, *i.e.*, as prosthetic groups or precursors of essential enzyme systems. Similarly, many microorganisms require preformed amino acids in much the same way that the mammal does.

In other respects the physiological potentiality of microorganisms goes far beyond that of any other living organisms. One gets the impression that these forms constituted a testing ground for a variety of physiological machinery, only some kinds of which have had sufficient survival value to persist on any large scale through the evolutionary process. While mammalian metabolism is simulated by some microorganisms, others are photosynthetic and resemble the green plants in the photochemical reduction of carbon dioxide or differ in that the photochemical reactions are coupled with the metabolism of inorganic sulfur compounds. Still others are chemoautotrophic in that they derive energy for the reduction of carbon dioxide from the oxidation of inorganic substrates such as hydrogen, or inorganic compounds of nitrogen, sulfur, iron, and manganese, and the nitrogen-fixing bacteria assimilate atmospheric nitrogen either alone or in symbiosis with leguminous plants.

Their sorting out by Winogradsky, Beijerinck, Hellriegel and Wilfarth, and others, beginning around the turn of the century. represents a remarkable achievement, not only in the isolation of physiological types of microorganisms for which there was no precedent, but also in the elucidation of the mechanisms of the cyclic transformations of the elements in nature and the microbial basis of soil fertility. Thus the autotrophic nitrifying bacteria, uniquely characterized by the oxidation of ammonia to nitrite, and of nitrite to nitrate, make possible the complete cycle of transformation of nitrogen compounds. The nitrogen leaking from the fixed form is more than replaced by microbial fixation, and the nature of the rejuvenation of depleted soil by cultivation of legume crops is made clear.

INFECTIOUS DISEASE

Sometimes new vistas are opened prematurely and not appreciated at the time, or too late and are anticlimactic, but occasionally new concepts coincide with an unusually receptive segment of the general stream of thought and seem to strike fire. The elucidation of the causes and possible prevention, control, and cure of rampant killing infectious diseases, with which almost every person was intimately familiar, was one of the last, and caught popular imagination as it developed.

The transition from the specific microbic etiology of fermentations and related phenomena to that of infectious disease was more readily reached than might appear. The analogies between the fermentable mixture and the susceptible individual, between active fermentation and clinical disease, and finally subsidence of active fermentation to recovery from and immunity to infectious disease were obvious. Further, the spread of contagion was already appreciated and something of the nature of the infectious agent indicated by epidemiological evidence as in Snow's studies on cholera, and those of Semmelweiss and Holmes on puerperal sepsis in hospitals.

The implications of Pasteur's studies on fermentation for infectious disease were almost immediately appreciated, notably by Lister, the British surgeon. He applied the basic principles to his own work, controlling infection in the operating room by liberal use of phenol, and so initiated, in 1867, an era of antiseptic surgery with a remarkable reduction in intercurrent infection and mortality. These practices were displaced within the next two decades by those of aseptic surgery, largely by von Bergmann in Berlin, as a consequence of a growing appreciation of the importance of infected persons as the primary source of sepsis.

It remained for the German physician Koch (1843–1910) to develop the experimental methods necessary to proof of a causal relation between bacteria and infectious disease. From the first applications of microscopy to the study of microorganisms it was clear that different morphological types existed and that these occurred in nature in mixed populations for the most part. It was evident also from the early studies on pyemia that morphological criteria did not suffice to differentiate and characterize the bacteria since morphologically identical forms differed markedly in patho-

genic properties. It was essential to separate such microorganisms from one another.

Initially this had been accomplished approximately, as in Pasteur's earliest work, by dilution in liquid culture mediums, and tubes showing growth in high dilutions of inoculum in which the occurrence of growth was irregular in replicates were assumed to contain only one kind of bacterium, descendants of the single viable parent cell present in the inoculum. Probably one of the greatest single contributions to technical bacteriology was the method of isolation in pure culture developed by Koch. It consisted of dilution of the inoculum and culture on a nutrient medium solidified as a gel by the addition of gelatin, and later agar, that served to separate viable cells from one another with the consequence that their progeny developed as discrete masses of cells of single ancestry, a clone in zoological terminology. Modern microbiology was in large part made possible by, and is based upon, this simple technique.

Although the fungus causing favus was described by Schoenlein in 1839, and the yeast-like organism of thrush by Langenbeck in the same year, the specific microbic etiology of infectious disease was first clearly established in studies on anthrax, an epidemic and highly fatal disease of cattle and other domestic animals. The microorganism now known as Bacillus anthracis had been observed by Davaine and Rayer in 1850 and by Pollender in 1849 in the blood and organs of animals dying of anthrax, and the disease was transmitted by Brauell in 1867 by the inoculation of normal animals with infected blood. It is generally conceded, however, that modern medical bacteriology began with Koch's studies on this disease in 1877, for in them he developed conclusive evidence of the causal relation of the anthrax bacillus to the disease of a kind subsequently known as satisfying Koch's postulates, i.e., isolation of the microorganism in pure culture, reproduction of the disease in experimental animals by inoculation with the pure culture, and demonstration of the microorganism in the experimental disease. Thus the kind of evidence required to establish the etiology of infectious disease was delineated, and, when shortly thereafter the solid medium technique for the ready isolation of bacteria in pure culture was developed, the last technical block fell into place.

These advances, coupled with the development of staining methods by Koch, Ehrlich, Weigert, and others, provided a tremendous stimulus to the study of infectious diseases that resulted in an immense accumulation of new knowledge within the ensuing two decades. Koch isolated the tubercle bacillus in 1882 and the cholera vibrio in 1883; Klebs described the diphtheria bacillus in 1883, and it was isolated by Löffler in the following year; Frankel discovered the pneumococcus in 1886, and the meningococcus was isolated in 1887 by Weichselbaum. Kitasato cultivated the tetanus bacillus in 1889, and in 1894 he and Yersin discovered the plague bacillus independently. The discovery of diphtheria toxin in 1888 by Roux and Yersin and of tetanus toxin by Kitasato in 1889 made possible some insight into the means by which bacteria produce disease.

Characterization of the pathogenic bacteria in morphological, physiological, and pathological terms, and study of their persistence under adverse conditions and behavior in the infected host were obvious and essential corollaries. Out of this kind of information there grew an understanding of the basic elements of the spread of infection from man to man, and from animal reservoirs of infection to man, either directly as in tuberculosis or indirectly as in bubonic plague, to give a firm foundation to epidemiology. Thus, while Snow deduced the presence of the causative agent of Asiatic cholera in the feces of diseased persons and its transmission to others by way of a common contaminated water supply in the famous Broad Street Pump epidemic in London in 1854. the nature of waterborne enteric disease became much more clear with the isolation and study of enteric pathogens such as the cholera vibrio and the typhoid and dysentery bacilli.

Effective control was an inevitable consequence of the developing understanding of infectious disease and its dissemination. The application of indicated control measures, chlorination of water supplies, pasteurization of milk, etc., coupled with widespread utilization of methods of artificial immunization, has been astonishingly successful. It has resulted in the virtual disappearance of many of the great killing diseases, such as smallpox, typhoid fever, Asiatic cholera, diphtheria, and plague, and a tremendous reduction in others, such as tuberculosis and

7 VIRUSES

scarlet fever, in many parts of the world. All of this stems in large part from implementation of the principle of specific microbic etiology of infectious disease.

VIRUSES

Early in the study of the etiology of infectious diseases, it became apparent that there were etiological agents of disease, apparently living, in that the diseases could be transmitted indefinitely in series, which could neither be seen with the light microscope nor cultivated apart from living host cells, i.e., were not cultivable on the lifeless mediums that supported the growth of bacteria. Iwanowski in 1892, and Beijerinck in 1899, observed the first of these agents, that causing mosaic disease of the tobacco plant, which Beijerinck described as a contagium vivum fluidum since it was present in bacteria-free filtrates of infected juice. A similar agent causing foot-and-mouth disease of cattle was described in 1897 by Löffler and Frosch, and the causative agent of vellow fever by the American Army Commission under the direction of Reed in 1900. Similar agents producing a transmissible lysis of bacteria were found by Twort in 1916 and d'Herelle in 1917, to give three groups of agents now known as the plant, animal, and bacterial viruses respectively.

The term virus steadily contracted from its meaning of any living agent, including bacteria, that was current prior to 1930, through the limitation filterable (or filtrable) virus because some of these agents would pass bacteria-proof filters, to the present significance of the term after about 1940. The extremely small size of the viruses was inferred from both inability to see them and from the ability of at least some to pass

through fine filters.

Over the next four or five decades accumulated information, based first on the ability of viruses to pass through some but not all collodion membranes of graded porosity, sedimentation rates in high speed centrifuges, and finally direct observation with electron microscope, showed that these agents ranged from a diameter of 200 mu. or just at the limit of resolution of the light microscope, to infectious particles as small as 10 m μ . Further, chemical analyses showed that the larger forms contained pro-

tein, polysaccharide, and lipid in biologically reasonable proportions and thus resembled bacteria, while the smaller forms appeared to be pure nucleoprotein. Some of the latter were, in fact, prepared in crystalline form: the first was tobacco mosaic virus which was prepared as needle-shaped paracrystals in 1935. Subsequently other plant viruses were prepared in the form of true crystals, viz., tomato bushy stunt virus as uniform rhombic dodecahedral crystals, and in 1955 a strain of the poliomyelitis, one of the smallest animals viruses, was prepared as bipyramidal tetragonal prisms. From data such as these, it was obvious that the viruses do not constitute a homogeneous group of infectious agents.

Related microorganisms, perhaps to be regarded as intermediary between the bacteria and the viruses, were described as the causative agents of a number of febrile diseases. The etiological agent of spotted fever was found by Ricketts in 1909, and subsequently da Rocha Lima, von Prowazek. and others showed that similar microorganisms caused fevers of the typhus group, tsutsugamushi and related diseases, and still later Q fever was found to be of similar etiology. These microorganisms, known as rickettsiae, were found to be as large as

small bacteria and so demonstrable under

the light microscope but, like the viruses.

to proliferate only in the presence of appriopriate host cells.

As a consequence of this dependence of the viruses and rickettsiae on living host cells, a variety of methods for their propagation in tissue culture were developed since the early part of the twentieth century. In such tissue cultures the host cells were found to be affected adversely, the cytopathogenic property of viruses, and it has been possible to demonstrate in this way the presence of viruses in materials from apparently normal human beings, especially from the upper respiratory tract and the intestinal tract. Propagation of viruses in the embryonated hen's egg was described in the early 1930's proliferation on the chorioallantoic membrane, in the allantoic cavity or yolk sac, or in the tissues of the embryo itself depending upon the agent and the route of inoculation. With the advent of antibiotics in the 1940's, it became possible to control the contamination of cultures of animal cells and tissues, resulting in the development of readily applicable methods of tissue culture for the propagation of viruses. The stimulus to virology was similar to that given to bacteriology by Koch's method of isolating bacteria in pure culture.

This dependence upon the host cell characterizing the viruses and rickettsiae raised the concept of parasitism to a high degree of intimacy. With one or two minor exceptions, these agents have been found to have no independent metabolism and thus to parasitize the metabolic mechanisms of the host cell, and some of them, particularly the bacterial viruses, appear to consist of little more than genic material which, on entry into the host cell, dominates its normal directive mechanisms to force the synthesis of new virus substance. Put more precisely, the virus parasitizes the high energyyielding reactions and the synthetic functions of the ribosomes of the host cell. It then became possible to show that nucleic acids, separated from the virus particle by phenol extraction or other methods, gave rise to the synthesis of complete virus on introduction into the host cell. Such preparations are known as infectious nucleic acid. The fundamental significance of such observations is obvious, and it has become more and more difficult, if indeed it is possible, to differentiate between the living and the nonliving.

IMMUNITY

It has long been a matter of common knowledge that the individual recovered from infectious disease was often specifically refractory to subsequent attacks of that disease, and that this refractory state, or acquired immunity, persisted in some instances for many years. The practice of deliberate exposure to the infectious agent in order to produce the disease, and therefore immunity, persists to this day in the case of a few diseases such as mumps and measles which are milder and less complicated in children than in adults. It reached a culmination of a sort in the practice of variolation, the deliberate inoculation of a susceptible person with pustular material from an individual with smallpox (variola). The disease so produced was less often fatal than naturally acquired smallpox and provided a more or less permanent protection against it. Variolation had been practiced in the Near East for an unknown time prior to its introduction to Western Europe in 1718 by Lady Mary Wortley Montague, wife of the British ambassador in Constantinople.

Artificial inoculation with an infectious agent of reduced virulence for man to produce a mild infection and consequent protection against naturally occurring disease began with the work of the Englishman Jenner. Noting the infrequent occurrence of smallpox in milkmaids who had been infected with cowpox (vaccinia), he undertook deliberate inoculation of man with vaccinia, followed by inoculation with variola some weeks later. He was able to report in 1796 that such prior infection conferred a high degree of protection against smallpox. This method of vaccination, or Jennerian prophylaxis, was widely practiced thereafter and remains in use today.

With the discovery of pathogenic microorganisms, it became possible to study immunity to infectious disease in a systematic way. Pasteur, working first with chicken cholera and later with anthrax and swine ervsipelas, showed that the basic principle uncovered by Jenner could be generalized to include disease other than smallpox. His most striking application of it was the development of rabies prophylactic, rabies virus that had been reduced in virulence for man by successive passages in the rabbit. Not long afterward the American workers, Salmon and Theobald Smith, found that inoculation with killed microorganisms could also stimulate the development of immunity. In 1890 von Behring and Kitasato laid the basis for antitoxic immunity through their discovery of tetanus and diphtheria antitoxins. This rounded out the approach to effective prophylaxis of infectious disease by acquired immunity produced in response to the artificial inoculation of modified microorganisms, killed microorganisms, or relevant products of microorganisms.

It became evident that the immune animal is characterized by, first, the presence of antibody, reacting specifically with microorganisms and their products, in the body fluids and localized in the globulin fraction

of the serum protein, and second, by an accelerated response of the phagocytic cells to the presence of microorganisms. The former, humoral immunity, was studied intensively by many workers such as Bordet, Ehrlich, and others, and two general approaches may be distinguished. The one has been concerned with the relation of humoral antibody to effective immunity. In some cases, such as antitoxic immunity, this seemed clear, but in others such as antibacterial and antiviral immunity, the immune state is more complex and presents many problems that are still unsolved.

The other has been concerned with the nature of antigenic specificity, which was elucidated largely through the work of Landsteiner in the 1920's, the nature of antibody, and that of the antigen-antibody reaction in physiochemical terms. Serology, the *in vitro* study of antigens and antibodies, led to the development of diagnostic serological reactions such as the Widal and Wassermann tests, and made possible the characterization of microorganisms on the basis of their constituent antigens by application of the methods of antigenic analysis.

The study of immunity associated with the activity of phagocytic cells, or cellular immunity, was developed initially largely by Metchnikoff in the late 1880's and thereafter. Proceeding from studies with *Daphnia*, he expanded the phenomenon of engulfment and destruction of invading microorganisms by polymorphonuclear leucocytes (microphages) and macrophages into a system of immunology. On this foundation Aschoff described and defined the free and fixed tissue phagocytes as the reticulo-endothelial system of cells. Further elucidation of the developmental potencies of cells of lymphoid origin by Maximov led to a general conception of the inflammatory reaction and cellular response to infection as a process of mobilization of phagocytic cells and destruction of microorganisms, followed by tissue repair through the development of macrophages into fibroblasts.

While cellular immunity and humoral immunity developed somewhat apart, it was early apparent that they are both facets of the host defense mechanism, obviously linked by the occurrence of circulating opsonic antibody, and by the intimate relation

of cells of the lymphoid-macrophage system to antibody formation.

CHEMOTHERAPY

One of Paul Ehrlich's many contributions to microbiology around the turn of the century was that to the chemotherapy of infectious disease. He urged the idea of the "magic bullet," a chemical compound, nontoxic to the host, that would search out and kill the invading microorganisms. Substances having a selective antimicrobial activity were known, but had arisen from folklore, or later on a trial-and-error basis not sanctified by age. Ouinine used for the treatment of malaria and representing the active principle of cinchona bark is a notable example of the former, and exploitation of the small antimalarial activity of methylene blue leading to the synthesis of Atabrine is an instance of the latter. Ehrlich implemented this concept by the synthesis and testing of hundreds of compounds of arsenic and eventually arrived at the parent compound salvarsan, which was an effective chemotherapeutic drug for the treatment of African sleeping sickness and syphilis. The antimicrobial activity of antimony was similarly followed out by others to give compounds that are reasonably effective in the treatment of infections with some of the animal parasites, but for many years all efforts to prepare antimicrobial substances effective in the treatment of bacterial infections fruitless.

In retrospect it is clear that the fallacy was the unquestioned acceptance of the working hypothesis requiring that a substance, to have promise, must have bactericidal activity. It became apparent later, and only since the early 1930's, that a bacteriostatic effect inhibiting reproduction of the invading microorganism is sufficient to tip the balance in favor of the host, with actual destruction of the bacteria accomplished by the host defense mechanisms.

Probably the first rational approach to the biological aspects of the problem of the chemotherapy of disease of bacterial etiology was that of Avery in the late 1920's. He put two kinds of information together. The one was the ability of microorganisms in general to decompose any kind of organic substrate, and the other the intimate association between the presence of capsular polysaccharide substance in the pneumococcus and the ability of that bacterium to cause disease. It seemed possible to isolate a microorganism that would specifically decompose the pneumococcal polysaccharide and separate the enzyme, catalyzing that decomposition for use as a therapeutic agent. This was accomplished but, while the cellfree enzyme preparation had therapeutic activity, it was too highly toxic to the host to have practical value.

A variation on a similar theme grew out of the study of microbial antagonisms, the adverse effect of one kind of microorganism on another when grown together in mixed culture. This effect was found to be due, in some instances, to the formation of a specifically toxic substance by the one kind of microorganism. The first of these found, pyocyanin, had in fact been known since the middle of the nineteenth century, prior to the work of Pasteur, Koch, and others, and had been extracted with organic solvents from the "blue pus" characterizing infections with the microorganism forming it.

The great majority of such substances, including pyocyanin, were found to be highly toxic to higher animals, but some proved to be of sufficiently greater toxicity to the microorganism than to the host that effective concentrations could be produced and maintained in the tissues of the infected host. Of these substances, the antibiotics, the first to be discovered was penicillin which was found in 1929, but its possible chemotherapeutic activity was not appreciated until 1940; prior to that time its greatest utility was that of facilitating the primary isolation of microorganisms, such as the influenza bacillus, that are relatively resistant to it. Of the other more widely known antibiotics, streptomycin was found in 1943. chloramphenicol in 1947, and the tetracyclines in 1948, 1950, and 1954. Although resting on a firm biological background, the discovery of these substances still remains on trial-and-error basis in that they are found through methods of screening vast numbers of microorganisms for activity.

The discovery of the chemotherapeutic activity of sulfonamides in the 1930's was also accidental. More than 1000 derivatives

of the parent compound, sulfanilamide, have been prepared, of which perhaps half a dozen are in common use. Since these substances antedated the discovery of the antibiotic chemotherapeutic agents, they were the first effective antibacterial drugs, and the effect of the introduction of these substances was nowhere more dramatic than in the treatment of puerperal sepsis. The fundamental importance of the sulfonamides, however, did not become apparent until 1940.

During the preceding decade a body of detailed information relative to the nutritional requirements of bacteria had been assembled, and study of the nature of the antibacterial activity of the sulfonamides had shown that it was primarily bacteriostatic rather than bactericidal. These apparently unrelated kinds of information were joined in 1940 by Woods's observation that the antibacterial activity of sulfonamides was specifically antagonized by p-aminobenzoic acid, an essential growth factor for some bacteria and utilized by very many if not all in the synthesis of folic acid. The structural similarity of p-aminobenzoic acid to the active portion of the drug molecule, p-aminobenzene sulfonic acid, suggested that the antibacterial activity of the latter was a result of a specific interference with the synthesis of an essential metabolite. This proved to be true and provided the first rational theory of chemotherapy of infectious disease in establishing the general principle of using structural and functional analogues of essential metabolites to exploit small differences, qualitative or quantitative, between the essential metabolic reactions of the host and parasite cells. Its general significance is illustrated in the chemotherapy of neoplastic disease with nucleic acid analogues.

MICROBIAL GENETICS

Variability of microorganisms was obvious from the beginning of their systematic study as alterations in certain of their properties, produced inadvertently as a consequence of maintenance on artificial culture mediums or as changes deliberately induced by laboratory manipulation. Alteration in the properties used for the differentiation

and characterization of microorganisms was found to occur with some facility, not as a consequence of an unusual plasticity, but rather because of their short generation time and occurrence as populations made up of huge numbers of individuals. Because of the relative simplicity of structure of microorganisms, especially the bacteria and viruses, the bacteriologist lacked a comparative anatomy that makes up the foundation of botany and zoology. He was forced to rely on such seemingly ephemeral characteristics as fermentation, nutritive requirements, and antigenic character, all of which varied, and had no means of knowing whether any of these, with the possible exception of the last, were biologically trivial or fundamental.

Studies in the 1920's with yeasts showed that, in these forms at least, the ability to ferment various carbohydrate substrates was genically determined in that a Mendelian segregation of characters of this kind occurred in the exchange of nuclear material during spore formation. This work was largely neglected by bacteriologists, and the demonstration that conjugation occurred between physiologically unlike bacterial cells did not occur until the 1940's.

While the importance of establishing the occurrence of genic control of the kind of characters used for the differentiation and identification of bacteria is unquestionable, microbiology contributed uniquely to, and markedly broadened, the basis of heredity through the occurrence of phenomena hitherto not demonstrable in other forms.

In 1928 it was shown that immunological types of living pneumococci could be changed by growing them in the presence of killed pneumococci of another type. Further refinement made it clear that the active principle in the dead pneumococci was a highly polymerized deoxyribonucleic acid that could be separated from the cells and purified in the test tube before addition to the living culture. This phenomenon was later found to occur also with other kinds of bacteria and is possibly related to the mechanisms of replication of certain of the bacterial viruses whose "invasion" of the host cell was found to consist of "inoculation" of that cell with viral deoxyribonucleic acid, in that in both kinds of phenomenon foreign nuclear material becomes functional in directing the metabolism of the host cell so

that it synthesizes a new substance and persists as an integral part of the genetic apparatus of the recipient.

Still another kind of modification of hereditary mechanisms was described in the early 1950's in which bacterial virus was found to transmit from one bacterial cell to another physiological characters that appear as stable inheritable elements in the new host cell. Finally, it has long been known that alteration in the physiological behavior of bacteria may be induced specifically by the environment even in the absence of cell multiplication, and this phenomenon of enzyme adaptation is conditioned by the specific substrate of each enzyme.

Out of this seeming disorder of microbial variation there has come, by way of analysis on a molecular basis, an orderly array of widely applicable general principles. This has led to a new era of biology, molecular biology, and modern genetics is, in large part, microbial genetics.⁴

RECONSIDERATION

The microbiologist has been something of a renegade, by necessity a master of many trades but a servant of none, and showing a certain lack of respect for the classical and established. Pasteur was not impressed with the opinions of Liebig and Berzelius, nor was it of any concern to Koch that no self-respecting medical man would work with a disease of domestic animals. The microbiologist has taken what he needed from zoology, botany, chemistry, physiology, pathology, medicine, etc., to create a new discipline, and it is apparent from even a cursory survey of the more important developments tracing its growth over a century that remarkable results were achieved.

It is literally true that the majority of the important infectious diseases were conquered in that they have been, or can be, so effectively controlled as to remove all but tuberculosis from the 10 leading causes of death in this and certain other countries, and thus has been made probably the largest single contribution to increased human life expectancy. New industries have been created, notably the fermentation industry with its ramifications into the production of antibiotics and vitamins of microbial origin, and

the biologicals and chemotherapeutic drugs of the pharmaceutical industry. Less obvious, but more important, has been a large group of unique contributions to biology, ranging from the creation of the new science of immunology, through much of biochemical physiology, to a greatly broadened concept of hereditary mechanisms to provide the basis for modern genetics and molecular biology.

Aside from such highly successful practical and theoretical applications, microbiology owes its important position in biological science to its general significance. There is no question but that microbiology has produced a change in man's conceptions of the world around him so sweeping as almost to deserve the term revolutionary. Up to the middle of the nineteenth century the character of many of the most familiar natural processes was entirely misunderstood; contemporary spontaneous generation of at least the lower forms of life was the generally accepted belief; infectious diseases were not differentiated from one another, and the most fantastic hypotheses were advanced to explain their existence.

Although the great mass of material phenomena elsewhere had been brought into apparent orderliness and system, here was a region in which the unscientific imagination rioted in mystery and extravagance. The penetration of this realm of obscurity by the discoveries of microbiologists gave the human race for the first time in its history a rational theory of disease, dispelled the myths of spontaneous generation, and set the process of decay and kindred phenomena in their true relation to the great cycle of living and nonliving matter.

The new conception of the microscopic underworld which microbiology brought into biological science must be reckoned as a conspicuous landmark and, insofar as it has changed the attitude of man toward the universe, may be regarded as one of the most important triumphs of natural science.

Chapter Two

LABORATORY METHODS*

The study of microorganisms in the laboratory by the various procedures of isolation in pure culture, cultivation, microscopic examination, and characterization by biochemical and immunological methods necessarily begins before detailed consideration of their nature and properties can be completed. The basic laboratory procedures are summarized here in didactic form, and their rationale will become apparent later.

STERILIZATION

The determination of the character and properties of a given species of microorganism is necessarily based on its study in pure culture, *i.e.*, its separation from other microorganisms. Since bacteria and other microorganisms such as fungi are ubiquitous, all material coming in direct contact with the microorganisms under study must be subject to preliminary sterilization. The sterilizing agent most commonly used is heat, dry or moist, but occasionally other methods, such as filtration of liquids through filters which retain microorganisms cultivable in the usual laboratory mediums, are desirable.

Glassware and instruments. The usual glassware includes flasks, petri dishes, test tubes and pipettes which must, of course, be scrupulously clean. Flasks and tubes are plugged with nonabsorbent cotton which prevents entry of bacteria after sterilization, and a cotton plug is inserted in the mouth end of the pipettes.

Petri dishes and pipettes may be placed in cans with covers or wrapped in paper to maintain sterility. Surgical instruments are wrapped in paper or towels, syringes separated and wrapped in paper, hypodermic needles placed in plugged test tubes, and other equipment similarly prepared.

Sterilization is effected in a hot air oven, electric or gas fired. The material to be sterilized is placed in the oven without crowding and the temperature raised to 170° to 180° C. and maintained for a period of not less than two hours. If appropriate temperature control equipment is not available, a slight browning of the cotton plugs is taken as indicative of sterilization, but this is a doubtful procedure.

In some instances sterilization by heating to dull red in a Bunsen burner flame is exceedingly useful as in the flaming of forceps tips, the platinum or nichrome wire needles and loops used for transferring bacteria, and the lips of test tubes before and after transfer of bacterial culture.

Surgical instruments, hypodermic needles and syringes, and similar equipment may be sterilized with respect to the vegetative forms of bacteria by boiling in water or 1 per cent bicarbonate solution for three to five minutes, but this does not suffice to destroy the spores of bacteria and fungi.

Culture mediums and other liquids. Material containing water cannot, of course, be sterilized by dry heat, but moist heat is a more effective sterilizing agent in any case.

Intermittent sterilization. As indicated before, boiling water does not provide a high enough temperature to bring about complete sterilization. Certain kinds of liquid culture mediums, however, are affected unfavorably by moist heat at higher temperatures, and these may be sterilized by intermittent sterilization. This is based on the assumption that the vegetative cells of microorganisms are destroyed at 100° C. in the presence of water, and that the surviving spores will germinate, and these vegetative cells will be destroyed in turn by exposure to 100° C. In practice the material to be so sterilized is exposed to free-flowing steam in an Arnold sterilizer for 30 minutes, removed and incubated until the next day and the steaming repeated, and a third incubation and steaming is included as a safety factor so to speak. The method is not too successful in that spores not infrequently show a delayed germination, and spores of obligate anaerobic bacteria

^{*}For the most part the methods described here are identical with or closely follow those of generally accepted procedures to be found in various compilations included among the references at the end of this chapter.

may not germinate. Sterilization by the intermittent method is, however, seldom required.

Autoclave sterilization. The most efficient method of sterilization is that effected by steam at temperatures above 100° C. which may be produced when the steam is under pressure. The devices employed in the use of steam under pressure include the common pressure cooker, autoclaves of various designs, and dressing sterilizers, which are autoclaves to which vacuum can be applied in order to dry fabrics that have been sterilized. Steam is generated directly in the apparatus or supplied by connection to a high pressure steam line.

As in the case of dry heat sterilization, the material to be sterilized must not be packed too tightly in the autoclave. The temperature is raised to 120° C. and maintained for a period depending on the material to be sterilized. As short a time as 15 minutes suffices for small volumes of material, as in culture tubes, loosely spaced, but if the tubes are packed in baskets, 20 minutes or possibly more should be allowed. For larger volumes, as in flasks, longer periods of exposure are necessary, e.g., for 500 ml. quantities 30 to 40 minutes. The time is that elapsing after the temperature is reached and until the pressure is shut off; the preliminary heating as pressure is built up and the slow fall in pressure at the end are not included. No attempt should ever be made to reduce the pressure rapidly after sterilization, for liquids will boil out of their containers.

Sterilization by filtration. It is often desirable to sterilize solutions such as cultures in liquid mediums, solutions of substances relatively unstable to heat such as certain sugars and the like, without subjecting them to heat at sterilizing temperatures. These may be sterilized by filtration through filters of such fine porosity that most microorganisms are held back. The method of sterilization by filtration is particularly useful in obtaining soluble products such as toxins.

Several kinds of filters are available. The Berkefeld filters are made of infusorial earth in three porosities, V (viel) or coarse, N (normal), and W (wenig); of these the V filters remove most but not all bacteria, the N filters usually sterilize, and the W filters are used for very small microorganisms. The Chamberland filter, of unglazed porcelain, is made in graded porosities, L1, L2, L3, etc., and of these the L3 is roughly equivalent to the Berkefeld N. The Seitz or Seitz-Werke filter is made of metal, and the filtering element is an asbestos pad which is the equivalent of the Berkefeld N filter. Sintered glass filters are available in a variety of porosities which in the Pyrex filters are designated C (coarse), M (medium), F (fine), and UF (ultrafine). The UF filter is bacteria-proof while the others are not. Cellulose ester membrane filters, marketed as Millipore filters, are available in a variety of pore sizes; type HA, with a pore diameter of 0.45 μ , is sterilizing filter.

Filtration is accomplished by a pressure differential which may be obtained by positive pressure on the liquid to be filtered, or negative pressure on the filtrate, and usually a differential of 20 to 30 cm. Hg suffices for reasonably rapid filtration without foaming. The Berkefeld and Chamberland types are prone to develop leaks, either as cracks in the filter candle, or where the candle is cemented to the metal portions, and the integrity of the filter must be controlled frequently by including a trace organism such as Serratia marcescens in the liquid to be filtered and by culture of the filtrate.

Whatever filter is used it must, of course, have been sterilized, usually in the autoclave, prior to use.

PREPARATION OF CULTURE MEDIUMS*

The nutritive requirements of microorganisms vary greatly; some will grow readily in the so-called synthetic mediums containing inorganic salts, including an ammonium salt, together with a simple organic compound such as glucose or asparagin as a source of carbon and energy. In general, microbiological mediums have been developed on a trial-and-error basis about a basic nutrient medium containing peptone and the water-soluble material, largely extractives, of muscle tissue. The source of the latter may be commercial preparations of meat extract, but a somewhat better medium is obtained if these substances are extracted from fresh meat, beef or veal for the most part.

The basal nutrient solution may be modified in a variety of ways. Thus, it may be solidified by the addition of gelatin or agar. or enriched with serum, ascitic fluid, defibrinated blood, and the like, to support the growth of the more fastidious bacteria. Various sugars may be added, together with an acid-base indicator, for the determination of the fermentative properties of bacteria; nitrate or tryptophan may be added to test for ability to reduce nitrate to nitrite, form indol from tryptophan, etc. Or culture mediums may be prepared which are differential and accentuate physiological differences, and specific inhibitory agents may be added to produce selective mediums which allow the growth of some kinds of microorganisms and suppress that of others. These various characteristics may be combined, of course, as in the case of an enriched medium which is both selective and inhibitory. Consequently, there is a great variety of bacteriological culture mediums, but they are in large part interrelated modifications of a basal nutrient solution. The constituents and method of preparation of a few of the

^{*}Many culture mediums are available commercially in dehydrated form, requiring only solution in water, dispensing, and sterilizing. Certain commonly used agar mediums are similarly available as poured plates or slants in plastic disposable "glassware."

commonly used culture mediums are reviewed here.

Basal mediums

Meat extract broth and agar. The medium usually has the following composition:

meat extract	3 gm.
peptone	5 gm.
(NaCl	5 gm.)
(agar	
distilled water	1000 ml.

It is necessary to include the sodium chloride if the medium is to be used for serological work or enriched with blood, and the agar is omitted if a liquid medium is desired. The ingredients are dissolved in water. Agar has the property of not dissolving or of its gels not melting unless it is heated to boiling, but its solution does not gel until the temperature reaches about 40° C. If agar is used it is necessary to boil the solution or heat it in the autoclave and clarify by filtration. The initial solution is usually slightly acid, and the reaction is adjusted to pH 7 by the addition of alkali.

Meat infusion broth and agar. The infusion mediums differ from the extract mediums in that the extractives are obtained by infusion of fresh meat, but otherwise the composition is the same, viz...

extract of 400 to 600 gm. fresh lean beef	or veal
peptone	
(NaCl	5 gm.)
(agar	
distilled water to	1000 ml.

The meat is ground in a meat chopper, suspended in 1 liter of distilled water, and infused overnight in the refrigerator. The following morning the fat is skimmed off with absorbent cotton and the infusion squeezed through muslin and made up to 1000 ml. The other ingredients are added, the reaction adjusted to pH 7, the solution heated to 100° C. for about 20 minutes, regardless of whether or not agar is used, filtered through coarse paper, and made up to 1000 ml. The heating is for the purpose of coagulating the tissue proteins dissolved during infusion so that they can be removed by filtration.

Mediums for biochemical tests

Sugar broths. The sugar broths are meat extract or meat infusion broth to which the required carbohydrate has been added to a concentration of 1 per cent. Unless the carbohydrate is stable to autoclave sterilization, it must be sterilized separately by filtration in concentrated solution and added aseptically to the sterile broth. It is customary to add an acid-base indicator dye, bromthymol blue or bromcresol purple, and the medium may be dispensed in culture tubes containing an inverted vial that fills during sterilization and serves to collect gas evolved in the fermentation of the sugar.

Nitrate broth. To test for ability to reduce nitrate, bacteria are cultured in nitrate broth, infusion or extract

broth containing 0.1 per cent KNO₃. The culture is tested for the presence of nitrite with sulfanilic acid and α -naphthylamine reagents.

The sulfanilic acid reagent is prepared by dissolving 8 gm. of sulfanilic acid in 1000 ml. of 5N acetic acid. The α -naphthylamine reagent (α -amidonaphthalene acetate) is prepared by dissolving 5 gm. of α -naphthylamine in 1000 ml. of 5N acetic acid and clearing by filtration through absorbent cotton.

To test for nitrite add 2 ml. of each of the two reagents to 3 to 5 ml. of culture; the development of a rose color, the nitroso reaction, indicates the presence of nitrite.

Tryptophan broth. The test for the production of indol from tryptophan can often be carried out with cultures in meat broth or peptone water, the latter containing peptone but no meat extract or infusion. The important factor is an adequate amount of tryptophan in the peptone. Some peptones are deficient, but a peptone marketed under the name Tryptone contains adequate amounts of the amino acid.

The presence of indol is tested for after two to four days' incubation of the culture by layering a small amount of Ehrlich's reagent on the surface of the culture; the development of a red color at the interface indicates the presence of indol. If a color does not appear within one minute, add a small amount, equal to that of the Ehrlich reagent, of saturated aqueous solution of potassium persulfate.

Ehrlich's reagent consists of 4 gm. of p-dimethylaminobenzaldehyde dissolved in a mixture of 380 ml. of ethyl alcohol and 80 ml. of concentrated hydrochloric acid.

Lead acetate agar. This medium is meat extract or meat infusion agar containing 0.05 per cent basic lead acetate and dispensed in culture tubes without slanting. It is usually prepared by mixing equal amounts of sterile double strength basal medium, i.e., containing double amounts of the ingredients, and sterile 0.1 per cent aqueous solution of basic lead acetate.

The medium is inoculated by stab, and the production of hydrogen sulfide from the sulfur-containing amino acids of the peptone is indicated as a blackening or browning of the medium.

Meat extract and meat infusion gelatin. These mediums are the basal mediums solidified by the addition of 12 per cent gelatin and are dispensed in culture tubes without slanting and inoculated by stab. They indicate whether or not gelatin is liquefied by the microorganism under study. Gelatin liquefies at 37° C., and gelatin cultures should be incubated at 22° C. In the case of those bacteria which will not grow at this lower temperature, the culture may be incubated in the usual way and after incubation tested for ability to solidify by chilling. Gelatin liquefaction sometimes occurs slowly, and cultures should be retained for not less than two weeks unless positive earlier.

Milk. Milk is an adequate culture medium for many bacteria without modification other than the addition of an indicator, bromcresol purple or litmus in an amount of 5 ml. of a 0.25 per cent alcoholic solution per liter. Fresh skim milk may be used, but skim milk powder is usually more convenient. One liter of medium is made from 150 gm. of milk powder, first rubbed up in a mortar and then diluted to volume. Medium prepared from powdered milk may be autoclaved, but that from fresh milk is best sterilized by the intermittent method

Because of protein and carbohydrate content milk cultures undergo a variety of biochemical changes, viz.,

- (1) The development of an alkaline reaction, usually after three to four days' incubation.
- (2) The development of an alkaline reaction with precipitation of the casein as a rennet curd, with or without reduction of the indicator.
- (3) The development of alkalinity and rennet curd precipitation, followed by peptonization or digestion of the curd, resulting in a clearing and brownish discoloration; the indicator is usually reduced by the time digestion is apparent.
- (4) Acid formation, usually in 24 hours, with or without reduction of the indicator.
- (5) Acid formation and precipitation of the casein, usually with reduction of the indicator.

Enriched mediums. Basal infusion mediums may be made richer by the use of special peptones, such as neopeptone and proteose peptone, and the addition of small amounts of glucose and phosphate buffer. In addition, fluids such as serum, ascitic fluid, or defibrinated blood may be added.

Blood agar. The most common and most useful enriched medium is blood agar-veal or beef infusion base to which defibrinated whole blood is added. The blood is usually taken from the rabbit, sheep or horse under sterile conditions and defibrinated as it is drawn by shaking with glass beads. The sterile infusion agar base is liquefied by heating, cooled to about 45° C., the sterile blood added to 10 per cent concentration, and the medium dispensed before it solidifies, usually in petri dishes or as slants in culture tubes. The entire operation is carried out under sterile conditions and the medium incubated for 24 hours to detect contamination, and then stored in the refrigerator. This medium is rich enough to support the growth of almost all the fastidious pathogenic bacteria and has the advantage that hemolysis is shown directly in the cultures.

Cystine blood agar. This is simply blood agar medium further enriched by the addition of 0.01 per cent cystine and 1 per cent glucose to the basal medium prior to the addition of blood as above. It is useful primarily in the cultivation of Pasteurella tularensis.

Chocolate agar. This medium is heated blood agar and is particularly useful for the cultivation of the gonococcus and meningococcus. Formulas vary somewhat, some workers preferring a beef heart infusion (see below) instead of muscle tissue infusion and proteose peptone instead of peptone. The basal infusion medium is enriched by the addition of defibrinated blood as in the preparation of blood agar, but after the addition of the blood it is heated slowly in a water bath until the medium has a chocolate brown color; if the heating is excessive the blood coagulates and the finished medium will contain clumps of cooked blood, so the temperature should not rise above 75° C, at the most.

Other infusions. The use of infusions of tissues other than beef or veal muscle is sometimes desirable for the cultivation of certain bacteria. Beef liver infusion is prepared in the same manner as that described for the other infusions and, for culture of Brucella for which liver infusion medium is particularly useful, the basal medium is enriched by the addition of 1 per cent egg albumin. Beef heart infusion is also prepared in the same manner as beef muscle infusion, and the basal medium completed by the addition of a peptone, sodium chloride, etc.

Löffler's medium. This medium is used primarily for culture of the diphtheria bacillus and consists of three parts of sterile beef serum and one part of meat infusion basal medium containing I per cent glucose. The serum is added to the sterile base, mixed, dispensed in culture tubes, slanted, and sterilized by the intermittent method. Sterilization may be carried out on three successive days in the autoclave at 15 pounds steam pressure without letting the air out, or it may be held at 15 pounds for 15 minutes and the air allowed to escape slowly while pressure is maintained and, when all the air has escaped, holding for an additional 15 minutes, and after sterilization allowing the pressure to fall very slowly. The medium is solid because of coagulation of the serum, and sterilization must be carried out carefully to avoid the formation of bubbles.

Blood culture medium (Kracke). This is a highly enriched medium containing beef heart infusion and brain suspension and is used primarily for blood culture of pathogenic bacteria in infections accompanied by bacteremia. Its composition is:

heart infusion	750 ml.
brain suspension	250 ml.
sodium citrate	i gm.
dextrose	10 gm.
peptone	10 gm.
dibasic sodium phosphate	2 gm.
sodium chloride	4 gm.

The heart infusion is prepared in the same manner as muscle tissue infusion described earlier. The brain suspension is prepared by macerating 500 gm. of fresh brain in water, straining through a metal strainer, and heating slowly to boiling with constant stirring. The heating coagulates the brain tissue and leaves it in a state of fine suspension; it must not be filtered. The other ingredients are added to the mixture of heart infusion and brain suspension, the pH is adjusted to 7.4, the mixture is dispensed in 50 ml. amounts in 100 ml. flasks (to leave room for an inoculum of 10 to 20 ml. of patient's blood) and sterilized by autoclaving. Cultures in this medium are essentially enrichment cultures and should be subcultured on appropriate agar mediums such as blood agar for streptococci and staphylococci and on liver infusion agar for Brucella.

Dorset's egg medium. This medium is used for the cultivation of the tubercle bacillus and consists of four fresh eggs and 25 ml. of 0.95 per cent sodium chloride solution. The eggs are scrubbed with a brush in soap and water, rinsed, dried, put into a wire basket and dipped into 95 per cent alcohol, drained, and the remaining alcohol ignited. They are then broken, using aseptic technique, and the whites and yolks placed in a sterile container. Twenty-five ml. of sterile salt solution is added, the whole mixed well with a sterile egg beater, dispensed in culture tubes and slanted, and sterilized by the intermittent method described for Löffler's medium.

Differential and selective mediums. The various differential and selective mediums have been designed to facilitate the isolation of one kind of bacteria in the presence of many other kinds, by accentuating physiologic differences and/or inhibiting the growth of the unwanted forms. Of the pathogenic bacteria, those most commonly encountered admixed with large numbers of closely related forms are the enteric bacilli, and many of the selective mediums are selective for these bac-

teria. The simplest of the purely differential mediums consist of meat extract or infusion agar base together with a sugar and an indicator. The most satisfactory indicator in most cases is bromthymol blue, and the colonies of the sugar-fermenting bacteria are yellow while those of the nonfermenters are blue. Of the selective agents bacteriostatic dyes are often used, and others include bile, tellurite, etc.

Endo's medium. This consists of meat extract agar to which has been added lactose and Schiff's reagent, basic fuchsin decolorized with sulfite. When the lactose is fermented aldehyde intermediates restore the color to the fuchsin and colonies of lactose-fermenting bacteria are red while those of the non-lactose-fermenters are white. The composition of the medium is:

hot melted extract agar	1000 ml.
sodium carbonate, 10% aqueous	10 ml.
lactose	10 gm.
sodium bisulfite, 10% aqueous	10 ml.
basic fuchsin, 3% alcoholic	10 ml.

The pH of the medium is raised by the carbonate and should be 7.6 to 8.0.

Eosin—methylene blue agar. This medium is sterile meat extract agar to which is added 5 ml. of a 10 per cent solution of lactose, 2 ml. of 2 per cent aqueous eosin, and 2 ml. of 0.5 per cent aqueous methylene blue. These solutions are added aseptically to the melted and cooled medium, and the mixture is dispensed in sterile petri dishes.

Deoxycholate-citrate medium. This medium is differential in that it contains lactose and neutral red as an indicator, and selective in that it contains bile salt, and is one of the most satisfactory and widely used mediums for the isolation of Salmonella and dysentery bacilli. It contains:

meat infusion	1000	ml.
peptone	10	gm.
agar	20	gm.
lactose	10	gm.
sodium citrate	20.6	gm.
sodium deoxycholate	5	gm.
lead chloride, 0.35% aqueous	1	ml.
ferric ammonium citrate	2	gm.
neutral red, 1% aqueous	. 2	ml.

The complete medium is not stable on storage. The peptone and meat infusion are mixed, the pH adjusted to 7.5. The solution is boiled for three minutes, lost water added, and filtered through paper. The agar is added to the hot solution together with 5 ml. of N NaOH, and it is allowed to stand for 15 minutes, then steamed at 100° C. for 20 minutes. Then the lactose, citrate, deoxycholate, and lead chloride are added. This may be stored and remelted for use. Just before use, the agar is heated to 100° C., the ferric ammonium citrate added, and the pH adjusted to 7.4 using phenol red as an indicator, and finally the neutral red is added and the medium dispensed in plates. Note that it is not autoclaved.

Bismuth sulfite medium (Hajna). This medium is used primarily for the isolation of the typhoid bacillus from fecal specimens and is highly specific for that organism. As originally developed it was difficult to prepare consistently, but Hajna's modification is highly satisfactory. It consists of a meat extract agar base con-

taining 0.5 per cent glucose, the bismuth sulfite mixture, and brilliant green. The bismuth sulfite mixture is prepared as follows:

- Dissolve 80 gm. of anhydrous bismuth sulfite in 400 ml. of hot water with stirring.
- (2) Make a paste of 24 gm. of bismuth citrate in 40 ml. of water, add 12 ml. of concentrated ammonia, and stir until a sol is formed. Dilute to 200 ml. with distilled water and mix to give a solution.
- (3) Mix (1) and (2), and add 42 gm. of anhydrous dibasic sodium phosphate and mix until dissolved.
- (4) Dissolve 4 gm. of ferrous sulfate in 50 ml. of distilled water containing 2 drops of concentrated hydrochloric acid, and add 40 ml. of this solution to mixture (3). Mix and boil gently for about 2 minutes until slate gray in color. This is the bismuth sulfite mixture, and it is stable for about 2 months.

For use, add 70 ml. of the bismuth sulfite mixture and 4 ml. of a 1 per cent aqueous solution of brilliant green to each 1000 ml. of the hot melted agar base and autoclave for not more than 10 minutes; then dispense in petri dishes. The complete medium may be kept for perhaps two weeks in the refrigerator without autoclaving and should be autoclaved just prior to dispensing.

Tetrathionate enrichment broth. Nutritive enrichment broths are used for preliminary culture of specimens followed by subculture on selective differential mediums. Tetrathionate broth and selenite F broth (see below) are very useful in the isolation of Salmonella from fecal specimens. The active agents in tetrathionate broth are bile salts, brilliant green, and tetrathionate, the last formed by oxidation of thiosulfate with iodine just prior to inoculation. Its composition is as follows:

Ţ	proteose peptone	5	gm.
ł	bile salts (Bacto)	1	gm.
. (distilled water	1000	ml.
. (calcium carbonate	10	gm.
	sodium thiosulfate	30	gm.
ł	brilliant green, 1% aqueous	11	ml.
i	iodine, 25% aqueous 2.5 ml. pe	r 100	ml.
	[iodine	25	gm.
	potassium iodide	20	gm.
	water		ml.

The peptone and bile salts are dissolved in water and calcium carbonate added, and autoclaved. The sodium thiosulfate and brilliant green are added to the sterilized medium, and it is dispensed in tubes or small flasks. Just prior to inoculation add the iodine solution in the proportion of 2.5 ml. per 100 ml.

Selenite F broth. This medium contains selenite as an inhibitory agent and its composition is:

sodium hydrogen selenite	4 gm.
peptone	5 gm.
lactose	4 gm.
sodium phosphates (anhydrous)	10 gm.
distilled water	1000 ml.

It is necessary to determine the proportions of acid and basic phosphates which will give a final reaction of pH 7.0 to 7.1 with the peptone and the lot or brand of selenite used. The ingredients are dissolved in warm water and then brought to a boil and dispensed. The medium is not autoclaved.

Chocolate-tellurite medium. This is a chocolate agar prepared by adding 10 per cent of defibrinated blood to meat infusion base agar as described earlier but modified by the addition of 150 ml. of sterile 0.3 per cent aqueous solution of potassium tellurite to every 1000 ml. of infusion base. It is used for culture of diphtheria bacilli.

Petragnani's medium. This is a medium used for culture of tubercle bacilli and contains malachite green to inhibit the growth of gram-positive bacteria and molds. Its composition is:

milk	900 ml.
potato flour	36 gm.
peptone	6 gm.
pieces of potato, size of an egg	6
eggs	24
egg yolk	6
glycerin	72 ml.
malachite green, 2% aqueous	60 ml.

The potatoes are cut into thin slices, the milk, potato flour, and peptone added, and the whole cooked in a double boiler for two hours with stirring. The eggs and egg yolks are broken together, the glycerin and malachite green added, and the mixture shaken well. The milk-potato mixture is cooled to 50° C., the egglycerin-dye mixture added and mixed well, and the whole is filtered through gauze, dispensed into tubes, slanted, and sterilized by the intermittent method described for Löffler's medium.

MICROSCOPIC EXAMINATION

The direct observation of microorganisms is an essential part of their study. Characteristics such as the shape and grouping of the cells, the presence or absence of structures such as capsules, flagella, and spores, the reaction to differential stains, and the like, are of considerable differential significance.

MOTILITY

Some bacteria have flagella which function as organs of locomotion and are analogous to the cilia of protozoa. The absence, or presence and number and location of flagella, is a characteristic of differential value. Flagella are too small to be seen in the usual stained preparations, but may be demonstrated by special staining procedures in which dye is deposited on them. The demonstration of flagella by staining methods gives results which are too uncertain to be useful as a routine procedure. Their presence, though not number and position, may be

inferred from a demonstration of motility, *i.e.*, a movement of translocation as differentiated from the random motion of brownian movement. This may be carried out in two ways, *viz.*,

- (1) Motility may be observed directly in suspensions of young cultures (usually not more than 18 hours old) suspended in a drop of saline or broth on a coverglass inverted on a hollow ground or "well" slide (the hanging drop preparation). Unstained bacteria are difficult to see, and the amount of light should be reduced to a minimum to give maximum resolution. Observation is facilitated by focusing the microscope on the edge of the drop and then moving the slide so that the drop is within the field of observation.
- (2) Motility may also be demonstrated by stab culture in "motility medium," a soft (0.5 per cent) agar nutrient medium dispensed in culture tubes. The medium is inoculated with the straight wire in a single stab penetrating several centimeters into the medium. Following incubation, the growth of nonmotile bacteria is found to be confined sharply to the path of the inoculating needle, while that of motile bacteria tends to diffuse out from the line of inoculation to give a fuzzy streak of growth.

STAINING

Bacteria may be stained or dyed with aniline dyes, more readily with the basic dyes.⁵ Staining may be with a single dye, or simple stain, most commonly crystal violet, methylene blue, or basic fuchsin, with mixed dyes or polychrome stains, or by differential methods based on the relative affinity of different bacteria or different structures of the bacterial cell for the stains used.

The so-called Romanovsky or polychrome stains are relatively complex mixtures of dyes that stain the constituents of protoplasm in contrasting colors-generally nuclear material red and cytoplasm blue. They are used primarily for staining blood and blood parasites such as trypanosomes and malarial parasites. In general, they consist of oxidation products of methylene blue (methylthionin) together with the parent substance and the compounds formed between these basic dyes and the acid dye eosin (eosinates). Of these, Giemsa stain is one of the most widely used. American Giemsa contains Azure A (asymmetrical dimethylthionin) eosinate, Azure B (trimethylthionin) eosinate, methylene blue eosinate and methylene blue chloride dissolved as a stock solution in methyl alcohol and glycerol. The material to be stained is commonly fixed in

methyl alcohol, and stained by flooding with a freshly prepared 1:10 dilution of stock solution of Giemsa.

The nature of the staining process has been a matter of considerable controversy, in large part as to whether it is fundamentally a physical or chemical process. It is now generally agreed that it is chemical in nature and the mechanism an ionic interchange between the basic dye and the acidic portions of the protoplasm—nucleic acids and their compounds—with the formation of insoluble dye-nucleotide compounds that do not diffuse out of the cell.

Stain solutions. The composition of stain solutions varies considerably in the literature. The several, frequently somewhat indefinite, formulas have been interpreted by the Biological Stain Commission and are given here in the emended form recommended by that Commission. In older formulas the dye content is often given as milliliters of a saturated alcoholic solution, and the accompanying table gives the solubilities of those most commonly used, in water and in 95 per cent alcohol.

Löffler's alkaline methylene blue

Solution A methylene blue (90% dye con-		
tent)ethyl alcohol (95%)	0.3 30	gm. ml.
Solution B		
dilute KOH (0.01% by weight)	100	ml.

Albert's diphtheria stain (Laybourn)

toluidine blue	0.15	gm.
malachite green	0.02	gm.
acetic acid (glacial)	1	ml.
ethyl alcohol (95%)	2	ml.
distilled water	100	ml.

Preparation of smears. Slides should be clean and free from all grease, and may be cleaned in soap and water, thoroughly rinsed, and stored in alcohol or xylol. Before use a slide is passed through the Bunsen burner flame two or three times. A drop of distilled water is placed on the cooled slide and a small amount of bacterial growth suspended in it, spread, and allowed to dry in air. The film is then fixed by passing through the burner flame two or three times, or, for some stains, by immersion in absolute methyl alcohol, glacial acetic acid, or other fixatives.

Procedure of the simple stain. The fixed smear is covered with stain, allowed to stand for 30 to 60 seconds, rinsed off with tap water, excess water removed by blotting, and allowed to dry in air. Bacteria are usually examined under the oil immersion objective, and the oil can be placed directly on top of the smear.

The Gram stain. Of the differential stains, Gram stain is one of the most valuable and most generally applied. The procedure is

Solubilities of Common Bacteriological Stains

essentially one of staining with crystal violet, mordanting with iodine solution, decolorizing with alcohol, and counterstaining with a dye of contrasting color. The stain was originally developed by the histologist Gram in an effort to stain bacteria in tissues differentially and it has been subject to many modifications. By this procedure bacteria are separated into two groups, those which retain the crystal violet and are said to be gram-positive, and those which are decolorized and stain with the counterstain and are gram-negative. The distinction is not always sharp for there is considerable variation in ease of decolorization, some gram-positive bacteria such as the pneumococcus become gram-negative after they die, and some bacteria are gramvariable. This last group is not large enough to detract from the practical value of the stain.

Both the crystal violet and the iodine are highly specific while the alcohol and the counterstain are not. Almost all other dyes, even methyl green which differs by only one methyl group from crystal violet, are unsuitable, either being retained or removed by alcohol whether or not the iodine is applied. A few other reagents, notably HgCl₂, may be substituted for iodine, and stannous chloride, pyrogallol, and freshly prepared solutions of hydroquinone show some slight activity.

However arbitrary Gram's method of staining may appear, the reaction is apparently associated with fundamental differences between the gram-positive and gram-negative organisms. There is, for example, a pronounced correlation between it and resistance to the bacteriostatic action of certain dyes and antibiotic substances and to the action of other chemical and physical agents. The nature of the Gram reaction has, therefore, been of considerable interest (see Chap. Three).

Procedure of the Gram stain. In addition to crystal violet and safranin staining solutions, Gram's* iodine solution is required as a mordant. Its composition is:

iodine	 . 1 gn	n.
potassium iodide	 . 2 gn	n,
distilled water	 . 300 ml	I.

^{*}This reagent is frequently given as Lugol's iodine; Lugol's iodine is defined in the U.S.P., and in the Gram stain is used as a 1:15 dilution.

The staining procedure is as follows:

- (1) The heat-fixed smear is stained for one minute with ammonium oxalate crystal violet.
- (2) Wash in tap water.
- (3) Flood with Gram's iodine solution and allow to stand one minute.
- (4) Wash in tap water and blot dry.
- (5) Decolorize 30 seconds with gentle agitation in 95 per cent alcohol, and blot dry.
- (6) Counterstain 10 to 30 seconds in safranin.
- (7) Wash in tap water, blot dry, and examine.

Acid-fast stain (Ziehl-Neelsen method). Certain bacteria, characterized by a high lipid content, cannot be stained by the usual procedure of the simple stain, and either heat or prolonged contact is required to drive the stain into the cells. Conversely, the stained forms are equally difficult to decolorize and resist decolorization with acid alcohol. These organisms are designated acid-fast and include the tubercle bacilli and related forms, the leprosy bacillus and certain of the actinomycetes.

Staining procedure

- Stain the smear for three to five minutes in steaming Ziehl's carbolfuchsin. An alternative procedure useful in diagnostic laboratories is to stain in the cold for 18 to 24 hours.
- (2) Rinse in tap water.
- (3) Decolorize in 95 per cent ethyl alcohol, containing 3 per cent by volume of concentrated hydrochloric acid, until only a suggestion of pink color remains.
- (4) Wash in tap water.
- (5) Counterstain for 30 to 60 seconds with alkaline methylene blue.
- (6) Wash in tap water, dry, and examine.

Fontana stain for spirochetes. The spirochetes stain very poorly or not at all by the usual simple staining procedure and are usually stained by a silver impregnation method.

Preparation of ammoniacal silver nitrate solution. Dissolve 5 gm. silver nitrate in 100 ml. of distilled water. Remove a few milliliters, and to the rest of the solution add, drop by drop, concentrated ammonia solution until the sepia precipitate which forms is dissolved. Then add, drop by drop, enough more of the silver nitrate solution to produce a slight cloud which persists after shaking. This solution is stable for some months.

Staining procedure

- Steam the heat-fixed smear in a solution of 5 per cent tannic acid in 1 per cent phenol for 30 seconds.
- (2) Wash for 30 seconds in running water.
- (3) Flood with ammoniacal silver nitrate solution, heat gently, and allow to stand 20 to 30 seconds after steaming has begun,
- (4) Wash in tap water, blot dry, and examine. The spirochetes appear as dark brown or black on a dark maroon field.

Capsule stain (Hiss's method). The bacterial capsule does not stain in the simple stain or Gram stain pro-

cedures. A number of methods of staining the capsules have been used of which that of Hiss is one of the most simple and effective. The stain is an aqueous solution of basic fuchsin or crystal violet, 0.15 to 0.3 per cent and 0.05 to 0.1 per cent respectively.

Staining procedure. The bacteria should be grown in ascitic fluid or serum medium for maximum capsule development, and bacteria grown on solid mediums should be suspended in serum for preparation of the smear. The smear is air-dried and fixed by heat.

 Stain with either aqueous basic fuchsin or aqueous crystal violet by heating gently until the stain steams.

- (2) Wash off the stain with 20 per cent aqueous copper sulfate solution
- (3) Blot dry and examine.

The bacterial cells are deeply stained and the capsules a faint blue or pink, depending upon which stain has been used.

Spore stain. Like acid-fast bacteria, spores are very difficult to stain and appear as unstained in the usual stained smear. The stain may be driven in by heat, and the Ziehl-Neelsen acid-fast staining procedure may be used with the modification that decolorization is less rigorous, *i.e.*, 95 per cent alcohol or absolute acetone should be used instead of acid alcohol.

Culture of Bacteria

Methods of obtaining pure cultures. When fluid culture mediums are inoculated with substances such as soil, water, or excreta, many kinds of organisms develop simultaneously side by side, and a heterogeneous mixture, or mixed culture, of bacteria results. Any technical procedure for obtaining pure cultures is dependent upon the isolation of a single viable bacterium which is allowed to multiply in a suitable culture medium. The first reliable method of isolation of pure cultures was devised by Koch in 1881. This method has proved so satisfactory that it has been employed to the present day with only minor modifications. If nutrient gelatin or agar is inoculated while fluid (for example, at 42° C.) and is then solidified and kept under favorable temperature conditions, many of the living bacteria that have been introduced are able to multiply. Since the bacteria cannot move about freely, but are fixed in the stiffened medium, the progeny of each organism form distinct masses or colonies. These colonies consist of many millions of bacteria and are readily visible to the naked eye or by means of a low power hand lens. If the colonies are not closely crowded, a pure culture may be obtained by touching a colony with the tip of a sterile needle and inoculating tubes of fresh culture mediums. In order to secure a large surface upon which the colonies shall be spread out and made easily accessible, the gelatin or agar after inoculation is poured while still fluid into sterilized flat shallow dishes (petri dishes) fitted with glass covers.

It will be clear that a given colony may arise from two or more parent cells if these remain attached or close together in the agar medium, and the colony will not be a pure culture in the event that the juxtaposed cells are of different species. This possibility has been investigated by McNew⁶ using the plant pathogen *Phytomonas stewarti*. He found that 98 per cent or more of the colonies arose from single cells, hence the probability of a mixed culture in a single colony is 0.02 or less. Successive plating or picking a number of colonies makes a pure culture a practical certainty. It is likely, however, that this figure differs for different bacteria, *i.e.*, staphylococci are more likely to remain attached than micrococci or bacilli.

It is self-evident that the pure culture so obtained is not only homogeneous with respect to kind or species of bacteria, but since the microorganisms are descendants of a single parent cell, they constitute what the zoologist or protozoologist terms a clone.

Technique of making plate cultures. Three tubes of agar (1, 2, 3), melted at 100° C., are placed in a water bath at 42° C., a temperature that is just above the solidifying point of agar and is not injurious to bacteria. Tube I is inoculated with a loopful of the material to be plated. The cotton plug is then replaced and the contents of the tube are mixed by carefully tilting back and forth and rotating the tube on its long axis. From this tube two loopfuls of agar are transferred to tube 2, and after mixing, two more loopfuls carried from tube 2 to tube 3. The contents of the several tubes are then poured into petri dishes. As soon as the cotton plug is removed, the mouth of each tube should be passed through the flame and inserted under the edge of the lifted petri dish cover and the agar quickly poured out. The covered petri dish may then be tipped cautiously back and forth to distribute the agar evenly before it solidifies. Agar plates placed in the incubator after solidification should be inverted in order to avoid spreading of the growth

through condensation of moisture on the surface of the medium. Even if there are a great many bacteria in the original material, the plate from tube 3 will probably contain the organisms in small enough numbers to develop well-isolated colonies. On the other hand, if there are very few bacteria in the material inoculated, plate 1 will probably present more satisfactory conditions. Gelatin plates are made in the same manner as agar except that gelatin may be cooled as low as 25° C. without solidifying.

Under exceptional conditions, such as work in the field, when petri dishes are not available, so-called roll tubes may be made. The tubes containing the liquid agar medium are tilted until the agar almost reaches the cotton plug. The tubes are then rotated in this position against a block of ice, and when the process is complete the test tube is coated on the inside with a thin layer of solid medium. In this way a considerable surface is obtained, and, after incubation, colonies are readily picked.

Quantitative dilution. It is sometimes of advantage before plating to make accurate dilutions of highly polluted fluids, such as sewage, in order to get colonies few enough in number to be well isolated. If there is reason to suppose that the number of bacteria is 200 per ml. or more, 1 ml. of the sample is mixed with 9 ml. of sterile water. If a higher dilution is required, proceed in a similar manner. See below.

One milliliter of each dilution is placed in a sterile petri dish, and 6 to 8 ml. of liquid cooled agar medium is added. The two are thoroughly mixed by tilting the petri dish back and forth and then allowed to solidify. After incubation the total number of colonies on the plates containing 50 to 200 colonies is counted, and the total number is multiplied by the dilution to give the number of organisms present in the original sample. Such bacterial counts are relatively inaccurate, errors of 10 to 15 per cent being common in even the most careful work, and must be regarded only as useful approximations.

Streak plates. Not infrequently mediums used for the isolation of the more fastidious bacteria are such that it is technically difficult to make the usual pour plates. The most common of these mediums are those which contain fresh blood. Such mediums are ordinarily prepared in quantity and sterile plates poured. These may be stored in the icebox until used. Dilution and consequent isolation of bacteria may be accomplished with these mediums by a process known as streaking. A sterile wire loop is dipped into the bacterial suspension and rubbed back and forth on the surface of the solid medium, making successive streaks as close together as possible. After incubation it will be found that at some point sufficient numbers of bacteria were rubbed off the loop to allow the development of individual colonies in the path of the streak. These may be picked and transferred to fresh mediums. Quantitative dilutions may be prepared in sterile broth or saline and 0.5 ml. of each dilution pipetted onto the surface of the medium and spread evenly by appropriate tilting.

Carbon dioxide tension. A number of bacteria, particularly the gonococcus, meningococcus, and Brucella, require an increased tension of carbon dioxide over that of ordinary atmosphere, commonly 10 to 15 per cent. Cultures of such bacteria are incubated in airtight jars in which a part of the air has been replaced by carbon dioxide. One or another of three methods is commonly used.

- (1) The most obvious and effective method is direct replacement in which the jar is a vacuum desiccator that is partially evacuated, 9 to 10 cm. Hg negative pressure, and the evacuated air replaced with carbon dioxide from a tank of the compressed gas. The method has the disadvantage that it requires a certain amount of equipment.
- (2) A simple and equally effective method is that of putting a short candle stub in the jar with the cultures, lighting it, and closing the jar. The candle burns for a short time, forming carbon dioxide, and then goes out. The partial pressure of carbon dioxide obtained is not subject to control, but the precise tension is not too important, and adequate amounts are formed.
- (3) Carbon dioxide may also be generated from sodium bicarbonate by the addition of sulfuric acid. The amounts required must be calculated on the basis of the size of the jar used so that 10 to 15 per cent of the total gas volume is the evolved carbon dioxide.

Cultivation of obligate anaerobes. Atmospheric oxygen is toxic to a group of bacteria designated the obligate anaerobes, which includes the bacilli of tetanus and gaseous gangrene, the botulinus bacillus, the Bacteroides, and anaerobic cocci. Various methods have been devised for the cultivation of these bacteria which center about the elimination of gaseous oxygen and which may be grouped under four general heads.

(1) Enriched mediums in deep tubes. Perhaps the simplest method is that of the so-called shake culture which is in an agar medium liquefied and boiled to drive out dissolved oxygen, inoculated when cool but still liquid, and solidified quickly in cold water. This is the basis of culture in the Veillon tube, a glass tube stoppered at both ends, which is sometimes used

(A)	To dilute	1:	10	use	1	ml.	of	sample	to	9	ml.	of	serile	water.
(B)	** ;	1:	100		ě.					99				
(C)	**	1: 1,	,000		çç		44	(A)	46	99	44			
(D)		1: 10	,000		46		44	(B)	• •	99				
(E)	"	1: 100.	,000		44		"	(C)		99	- 64		. 44	44
(F)	"	1:1,000	,000		6,6		"	(D)		99	44			

in the isolation of obligate anaerobes in pure culture; the tube may be broken or the column of agar medium forced out into a sterile petri dish and cut at the various points where isolated colonies occur deep in the medium.

A somewhat simpler method of culture in liquid medium is based on the use of a rich medium to which is added a piece of fresh sterile tissue such as rabbit kidney. Such mediums show strong oxygen uptakes as a result of the respiration of the fresh tissue, and the depths of the medium are anaerobic. As soon as growth is initiated the evolution of gas, usually from contained glucose, is vigorous enough to prevent solution of atmospheric oxygen, and the culture remains anaerobic.

(2) REMOVAL OF OXYGEN BY COMBUSTION. Oxygen may be removed from the gaseous environment of cultures incubated in sealed jars in a number of ways. Sufficiently anaerobic conditions can frequently be obtained by saturating a piece of filter paper with alcohol, placing it in the jar and igniting, and sealing the jar immediately. Similarly, a small metal container filled with chalk may be put into a jar, a piece of phosphorus placed in it, and the jar sealed immediately. The phosphorus pentoxide formed will dissolve in a small amount of water placed in the bottom of the jar and is not harmful to bacterial cultures, but the phosphorus begins to burn again when the jar is opened, and the method is somewhat dangerous.

By far the most convenient combustion method is that in which the oxygen is removed by combination with hydrogen in the presence of heated platinized asbestos. Jars designed for this purpose with platinized asbestos heated by a small electric coil have been described by Brewer and are termed Brewer anaerobic jars. The jar rim is sealed against both positive and negative pressure and hydrogen or illuminating gas run in to give some positive pressure. The electric current is turned on, and the oxygen is burned out in the presence of the combustible gas and catalyst. This method is considerably more reliable than the combustion methods described above but is somewhat dangerous; if the platinized asbestos is finely divided, heating is unnecessary.

(3) CHEMICAL ABSORPTION OF OXYGEN. Contained oxygen in sealed jars may also be removed by chemical methods, of which the most widely used is a mixture of pyrogallic acid and alkali in the bottom of a vacuum desiccator. The jar should be closed immediately on addition of the reagents, and it is preferable to mix after closing by tilting or spilling one reagent into the other. Excess alkali is to be avoided. The reagents are 20 per cent aqueous sodium hydroxide and 40 per cent aqueous pyrogallic acid mixed in proportions of 5 ml. of alkali to 2 ml. of pyrogallic acid. The alkali-pyrogallic acid method is applicable to single culture tubes; a stopper of absorbent cotton is pushed down to leave about an inch of space above it, pyrogallic acid and sodium hydroxide placed in this space to saturate the cotton, the tube closed at once with a tight-fitting rubber stopper and turned upside down and incubated in that position. It may be used also for the anaerobic incubation of a single petri dish in combination with the Spray dish, which is a false bottom, so to speak, over which the medium-containing half of the petri dish is inverted and sealed. The Spray dish is divided by a ridge in the center; 4 ml. pyrogallic acid is put on one side and 10 ml. of alkali on the other; after sealing on the petri dish bottom, the two are mixed by tilting.

(4) DISPLACEMENT OF AIR BY AN INERT GAS. The air contained in an anaerobic jar may be mechanically displaced by an inert gas, commonly hydrogen since tanked nitrogen contains sufficient oxygen to inhibit the growth of the fastidious obligate anaerobes. A jar with two connections, one reaching to the bottom, designated a Novy jar, may be used with tanked hydrogen. The hydrogen is run in from the bottom of the jar until the contained air is displaced. The air in an anaerobic jar may also be displaced by hydrogen evolved in the reaction between sulfuric acid and powdered chromium metal.

Control of anaerobiosis. It is usually desirable to include an indicator of anaerobiosis in an anaerobic jar to indicate that anaerobic conditions have been obtained and are maintained, i.e., there is no leakage of atmospheric oxygen into the jar during incubation. The usual indicator is a tube of methylene blue prepared as follows: equal parts of N/160 sodium hydroxide, 0.015 per cent methylene blue and 6 per cent sterile aqueous solution of glucose are mixed, boiled just before the jar is to be sealed until the methylene blue is reduced, and the open tube put into the jar. So long as it remains colorless anaerobic conditions are maintained.

SYSTEMATIC STUDY OF BACTERIA IN PURE CULTURE

The characteristics of bacteria that are of significance in their identification must be studied in some uniform fashion, not only with regard to the methods used but also as to the characteristics that shall be considered of first importance. Although the classification of bacteria is in a somewhat dubious state, this uncertainty has resulted largely from a relatively hazy comprehension of the fundamental biologic significance of some differential characteristics and consequent doubt as to the proper relative weight to be assigned to them in the arrangement of the finer subdivisions of taxonomic schemes. The main lines of approach, however, are clear, and whatever their relative biologic significance may prove to be, the readily determinable characteristics of bacteria serve the practical purpose of distinguishing these microorganisms.

There are four general categories which, in the order of the fineness of distinction they make possible, are: (a) morphology, both gross and microscopic; (b) physiologic capabilities in terms of biochemical reactions; (c) pathogenicity for experimental animals; (d) immunological character.

The preliminary and basic study of a bacterium lies in the systematic determination of its cultural characters. The most important of these are:

(A) Morphology

- gross morphology—that of colonies of the organism with respect to size, texture, color, shape, etc.
 - (a) on nutrient or infusion semisolid mediums(b) on special mediums

(2) microscopic morphology, including

(a) size, shape, and grouping of the organisms

(b) presence or absence of spores

(c) motility

(d) presence or absence of capsule

(e) staining reactions

(B) Biochemical reactions

- (1) the fermentation of sugars, usually dextrose, lactose, and sucrose, although others may be included together with the hydrolysis of starch
- (2) liquefaction of gelatin

(3) formation of indol

(4) reduction of nitrate to nitrite

(5) production of hydrogen sulfide

(6) special biochemical tests, such as the Voges-Proskauer reaction, the methyl red test, hemolysis on blood agar, etc.

Such preliminary examination ordinarily affords a great deal of information about a given bacterial culture. The feasibility of additional study rests firmly on the foundation laid down by the studies outlined above.

Various attempts have been made to systematize the study of bacteria. One of the most successful of these has resulted from the efforts of a Committee on Bacteriological Technique of the Society of American Bacteriologists (now the American Society for Microbiology).

ANIMAL INOCULATION

An indispensable adjunct to the study of the pathogenic bacteria is the experimental animal. Animals are used not only for the study of the pathology of infectious disease and as an aid in the isolation of some bacteria in pure culture, but also for the experimental production of immune serums and studies on the various manifestations of immune phenomena. The maintenance by animal passage of such infectious agents as the viruses, which cannot be cultivated on lifeless mediums, is common also. The animals generally used are rabbits, guinea pigs, white mice, and white rats, although in special cases others, such as rhesus monkeys, are necessary.

Routes of inoculation. Experimental animals may be inoculated by a variety of routes, usually one or another being prefer-

able under the particular circumstances. The common routes of inoculation are intradermal, subcutaneous, intramuscular, intraperitoneal, and intravenous. Other routes such as intraocular, intracerebral, and intrathecal may be desirable at times. In any case, inoculation is carried out with a syringe and hypodermic needle, the capacity of the syringe and size of the needle used depending upon the quantity of material to be injected and the route of inoculation. The site of inoculation must be prepared by removal of the hair by shaving or a depilatory, followed by disinfection by swabbing with alcohol, tincture of iodine, etc. The syringe and needles have, of course, been previously sterilized by dry heat or by boiling.

Intracutaneous inoculation. Material inoculated intracutaneously is inoculated into the skin. A fold of skin is pinched up and the needle inserted, lumen up, as superficially as possible. A raised white spot showing the pits of the hair follicles indicates a successful injection. Not more than 0.2 ml. may be inoculated by this route.

Subcutaneous inoculation. Subcutaneous inoculation requires considerably less skill on the part of the operator. A fold of skin is pinched up as before and the needle inserted through the skin to its full length. The injected material forms a bleb or blister. The amount that may be injected by this route depends upon the size of the animal.

Intramuscular inoculation. In the intramuscular inoculation, the needle is inserted deep into the muscular tissue, usually the posterior muscles of the thigh or the lateral thoracic or abdominal muscles.

Intraperitoneal inoculation. Intraperitoneal inoculation is carried out as one would a subcutaneous injection on the abdomen except that after the needle penetrates the skin, it is held at right angles to the peritoneal wall and thrust through into the peritoneal cavity.

Intravenous inoculation. Intravenous inoculation may be carried out in a variety of ways, the choice depending upon the size of the animal. Rabbits are conveniently inoculated in the marginal vein of the ear. The needle is inserted through the skin and into the vein from the side. If the needle is within the vein, blood will disappear in the vein from the point of the needle onward as the material is injected. Needless to say, the injection should take place in the direction of blood flow. Guinea pigs may be inoculated into the large superficial vein on the dorsal and inner side of the hind leg or into one of the external jugular veins. Both require anesthesia of the animal and a small incision, which may be later closed with a stitch or collodion. Rats may be inoculated in an external jugular vein and mice in one of the lateral veins of the tail.

Drawing blood. Blood may be taken from the rabbit from the marginal vein of the ear or directly from the heart. The appropriate area is shaved and swabbed with alcohol. If blood is to be taken from the ear, the marginal vein is cut across with a razor blade and the blood allowed to drop into a centrifuge tube or test tube. Flow may be hastened by preliminary application of a towel wrung out of hot water to induce hyperemia. When

blood is to be taken directly from the heart, a 30 to 50 ml. syringe is used and the needle inserted between the ribs at the point of maximum pulsation and thrust into the heart, care being taken to injure the pericardium as little as possible. Blood is most conveniently taken from smaller animals by this means.

Postmortem examination. The autopsy of experimental animals dead of infection is often highly desirable. Not only may cultures be taken, but the gross and microscopic pathology is usually of significance. The animal is fastened down on a board, ventral surface up. It is good practice to have the board in a larger enameled tray to reduce to a minimum the danger of spreading infectious material. When cultures are to be taken, the animal must be opened with sterile instruments. Usually several pairs of scissors and forceps and two or three scalpels are necessary. The site of inoculation is examined for ulcerative or other changes, and the hair and skin are disinfected with cresol or Lysol.

The skin is incised from the pubis to the neck and cut at right angles at the ends of the incision. The two flaps may be laid back by separation of the cutaneous from the underlying muscular tissue with a scalpel. The condition of the subcutaneous tissue and of axillary and inguinal lymph glands may be noted. The peritoneal fluid may be cultured by searing a small area on the surface of the abdomen with a hot spatula and puncturing with a syringe and needle or a Pasteur pipette into which the fluid may be aspirated. The abdominal cavity is opened with fresh instruments, and the flaps are laid back as above. The condition of the abdominal organs, such as spleen and liver, may be noted and cultures taken by first searing the surface and then either puncturing and aspirating fluid with a syringe and needle or a Pasteur pipette, or by removing a small piece of tissue and placing it in nutrient medium. Likewise, pieces of tissue may be removed and placed in fixing fluid for subsequent sectioning. Again with fresh instruments, the costal cartilages are cut to make a V-shaped incision, and this flap is laid back over the head, exposing the thoracic cavity. Any gross pathology may be noted, cultures may be taken from heart's blood and elsewhere if desirable, and pieces of tissue removed for fixation and sectioning. The animal is disposed of by incineration.

It is obviously impossible to define postmortem procedure rigorously. The lymphatic system of guinea pigs dead of tuberculous infection will be of considerable interest. Those dying of diphtheritic toxemia or infection will show characteristic lesions of the adrenals. In some diseases the important postmortem findings may be in the brain and spinal cord. The routine of examination will be determined, therefore, by the particular disease under consideration or, if this is not known, by the symptoms exhibited by the animal before death.

A number of precautions must be observed in the autopsy of animals dead of infectious disease. If cultures are to be taken, fresh sterile instruments must be used at each stage. Instruments once used should be returned to the boiling water sterilizer or placed in tray containing Lysol or, if to be used again, laid down on the edge of the tray with all sharp edges and points inward. Extreme care must be taken to avoid disseminating infectious material. With certain highly contagious diseases such as tularemia, rubber gloves may be desirable. Boiling water sterilization (five minutes) of used instruments is sufficient except with the sporeforming organisms such as anthrax and tetanus, in which case the instruments should be allowed to stand in a solution of Lysol or cresol.

Propagation of Viruses and Rickettsiae*

The viruses and rickettsiae are set apart from the bacteria by their inability to proliferate except in the presence of living host cells (Chap. Four). The propagation of these microorganisms under experimental conditions in the laboratory, apart from infection of the intact susceptible animal, is dependent upon the use of such living host cells. Appropriate host cells are most readily available as the variety of cells and tissues of the embryonated hen's egg, and as mammalian cells of varied origin maintained as cell or tissue cultures.

THE EMBRYONATED EGG^{3, 13}

The sterile, rapidly multiplying, and diversified cells of the embryonated egg include those of the investing membranes as well as those of the embryo proper. The

*This section was prepared by Dr. Dorothy Hamre.

former may be infected by inoculation into the surrounding fluid, as by inoculation of the yolk sac or the allantoic cavity, or directly as in the case of the chorioallantois. The variables, dependent upon the agent being studied, include the age of the embryo, the type of diluent used for the inoculum, the route of inoculation, and the temperature of incubation after inoculation. For example, the typhus rickettsiae are grown in the yolk sac of the six- to eight-day embryo, influenza virus in the allantoic cavity of the 10- to 11-day embryo, and vaccinia and herpes simplex viruses on the chorioallantoic membrane of the 12- to 13-day embryo. Or the embryo may be inoculated directly, as for instance intracerebrally or intravenously, or may be removed, minced and grown as a tissue culture (see below).

Fertile eggs from disease-free flocks should have white shells to facilitate observation by transillumination. When they are to be used for the propagation of rickettsiae or viruses of the psittacosis-lymphogranuloma venereum group, the flock should not be fed diets supplemented with the broad-spectrum antibiotics. The eggs can be stored, prior to incubation, for as much as a week at 5° to 20° C. with little loss of viability. The eggs are incubated at 37° to 37.8° C. at a relative humidity of 40 to 60 per cent in a forced draft incubator, *i.e.*, a conventional egg incubator. On the fifth day, they may be candled and nonviable embryos and infertile eggs discarded. After appropriate further incubation, the egg may be inoculated by any of several routes.

Yolk sac. *Inoculation*. A small hole is drilled or punched, without rupturing the shell membrane, in the center of the shell over the air space at the large end of the egg. After disinfection of the area with iodine-alcohol, the inoculum is introduced by means of a syringe with a 22 g. 1½-inch needle, which is inserted until the tip of the needle is about in the center of the egg. Amounts of 0.25 to 1.0 ml. can be injected. After the needle is withdrawn, the area around the hole is again disinfected and the hole sealed off with melted paraffin, collodion, or nail lacquer.

Harvest. After disinfection by swabbing with iodinealcohol, the shell over the air sac is removed with sterile scissors or forceps. The exposed shell membrane and chorioallantoic membrane are cut away, and the contents of the egg tipped into a sterile petri dish, with a long forceps guiding the material. The yolk sac is then dissected away from the other membranes and placed in a second petri dish which has been weighed. After determination of the wet weight of the yolk sac, it is transferred to a sterile flask or bottle partially filled with glass beads. A suitable volume of diluent is added, and the flask is closed with a sterile rubber stopper and shaken by hand or on a bottle shaker for about 20 minutes. The resulting suspension is centrifuged to remove cellular debris, and the supernatant fluid, containing the virus, is decanted.

Amnionic cavity. Inoculation. The eggs are candled, the air space outlined, and the position of the embryo noted. The shell over the air sac is disinfected and a hole about 1.5 cm. in diameter cut in the center with sterile scissors. The shell membrane is moistened with saline to make it transparent, and a small hole made in the chorioallantois over the embryo with fine-tipped forceps such as iris forceps, taking care not to rupture large blood vessels. The amrionic membrane is picked up with the forceps and brought up through the hole in the chorioallantois in a tentlike fold. The inoculum is injected with a syringe and 25 g. needle into the fold. The membrane is then released, and will drop back into its original position. The hole is sealed with strips of Scotch tape; the gummed surface of this tape is sterile as it is peeled from the roll.

Harvest. The taped shell down to the edge of the air sac is cut off and the exposed shell and chorioallantoic membranes removed with sterile scissors. The allantoic fluid is removed with a pipette. The amnionic membrane is then picked up with sterile forceps and the fluid inside, containing the virus, is removed with a capillary pipette. If there is very little fluid, the sac can be washed out with a suitable diluent. If desired, the embryo may then be removed and appropriate tissues harvested.

Allantoic cavity. Inoculation. The egg is candled, the edge of the air sac outlined, and a line intersecting the edge made at a position where there are no large blood vessels. A small hole is drilled on this intersecting line about 3 mm. above the edge of the air sac. The inoculum, usually 0.2 ml., is introduced by means of a syringe and 25 g. needle, which is inserted through the hole to a depth of about 1 cm. in a line parallel to, but not touching, the shell. The hole is disinfected and sealed with paraffin, collodion, or nail lacquer.

Harvest. The eggs are chilled overnight at 4° C., or for a shorter time in a freezer, to prevent bleeding. After the shell over the air sac is disinfected, it is removed and the exposed shell membrane over the choricallantoic membrane carefully stripped away with sterile

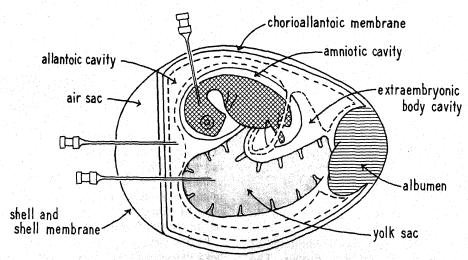

Figure 2. Diagrammatic representation in sagittal section of the embryonated hen's egg 10 to 12 days old. The hypodermic needles show the routes of inoculation of the yolk sac, allantoic cavity, and embryo (head). The chorioallantoic membrane is inoculated after it has been dropped by removing the air from the air sac.

forceps. In the chorioallantoic membrane, away from major blood vessels, a hole is made with a sterile applicator stick, which is then used to hold the embryo and membranes away from the pipette used to remove the allantoic fluid containing the virus.

Chorioallantoic membrane. Inoculation. The egg is placed horizontally on a tray, and a new air sac made by dropping the chorioallantoic membrane as follows: After disinfection of the site, a small hole is made in the center of the large end of the egg over the air space. A second hole is drilled, or punched with a dull punch, collared to prevent penetration of more than 0.8 mm., in the center of the uppermost portion of the egg. It is essential that neither the shell membrane nor the chorioallantoic membrane be damaged in this process. A drop of saline is placed over the hole, and the shell membrane carefully broken by means of a sterile penpoint with a small ball tip or slightly upturned tip; the penpoint is inserted through the drop of saline between the shell and the shell membrane, and then slightly depressed and removed. This usually produces a very small rent in the shell membrane. Then slight suction with a rubber bulb over the hole in the large end of the egg will result in the chorioallantoic membrane's dropping away from the shell. The inoculum is introduced through the hole above the dropped membrane with a syringe and 25 g. needle. The hole is then sealed with Scotch tape.

Harvest. The shell above the dropped membrane is disinfected and removed with sterile scissors to expose the membrane. The chorioallantoic membrane is cut out and placed in a sterile petri dish, and spread out and examined for lesions before weighing and grinding. After grinding in a sterile mortar with a small amount of sterile alundum, the appropriate diluent is added, mixed well with the ground tissue, and the suspension centrifuged to remove debris. The supernatant fluid contains the virus.

TISSUE CULTURE^{9, 14}

Although animal cells and tissues have been grown in culture for many years, it was not until the antibiotics became available to control the vexatious problem of contamination that successful culture could be carried out generally. As now practiced for the propagation of viruses, tissue culture can be carried out in almost any microbiological laboratory provided the necessary attention is given to exceptional cleanliness of glassware and avoidance of bacterial and fungal contamination. The former includes washing glassware in special detergents and rinsing it in double-distilled or distilled and deionized water, while the latter involves use of a hood or small cubicle in the laboratory away from drafts, together with antibiotics in the salt and nutrient solutions.

Culture methods in which the cells are grown on the surface of glass test tubes or bottles are the most frequently employed, and will be described briefly here in terms of examples. Details of these and other tissue culture methods may be found elsewhere. The solutions required are buffered saline and balanced salt solutions, and growth and maintenance mediums.

Salt solutions. One of the most commonly used buffered saline solutions is the phosphate-buffered saline (PBS) of Dulbecco and Vogt. It has the following composition:

(1)	NaCl	8.0	gm.
11.	KCI	0.2	gm.
	Na ₂ HPO ₄	1.15	gm.
	KH ₂ PO ₄	0.2	gm.
	double-distilled water	800	ml.
(2)	CaCl ₂	0.1	gm.
	double-distilled water	100	ml.
(3)	$MgCl_2 \cdot 6 H_2O \dots$	0.1	gm.
	double-distilled water	100	ml.

The three solutions are sterilized separately by autoclaving, and mixed when cool.

The balanced salt solutions (BSS) usually used are Hank's or Earle's; the composition of these is given in the accompanying table. Usually phenol red in a concentration of 1 to 5 mg. per cent is added as an acid-base indicator. The BSS are bicarbonate buffered, and therefore must be sterilized by pressure filtration to avoid loss of carbon dioxide. It follows also that culture tubes and bottles must be tightly stoppered to maintain acid-base equilibrium, and when tissues are grown in petri dishes, an atmosphere containing 5 per cent carbon dioxide is required.

Culture mediums. The culture mediums may resemble bacteriologic mediums as in the case of 0.5 per cent lactalbumin hydrolysate in Hank's or Earle's BSS. Other basal mediums are chemically defined, such as Medium 199 of Morgan, Morton and Parker, and Eagle's basal medium. There

Balanced Salt Solutions (grams per liter)

	EARLE'S	hank's
NaCl KCl CaCl ₂	6.80 0.40 0.20	8.00 0.40 0.14
$MgSO_4 \cdot 7 H_2O$ $Na_2HPO_4 \cdot 12 H_2O$ $NaH_2PO_4 \cdot H_2O$	0.20	0.20 0.12 -
KH₂PO₄ NaHCO₃ Glucose	2.20 1.00	0.06 0.35 1.00

are many such basal mediums for tissue culture.

Growth mediums. To support the growth of tissues, such basal mediums require supplemental serum, usually to 10 per cent, the species of serum depending upon the kind of cells being cultured.

Maintenance mediums. When the tissue culture is fully developed, e.g., a continuous sheet of cells covers the glass surface of the kind of culture described here, the growth medium is removed and a maintenance medium substituted during the period of viral replication. In maintenance mediums, the serum added to the basal medium is reduced in amount, or even omitted in some cases, the precise conditions varying with the kind of culture.*

To all of these solutions and culture mediums antibiotics must be added to prevent microbial contamination. These are: penicillin G, 100 units per ml.; streptomycin, 100 µg. per ml.; and Fungizone, 1 µg. per ml.

Preparation of tissues. Two types of tissue cultures are most often used in virus studies, viz., primary cultures which are cultures of tissue or organ explants that tend to die out on subculture and are necessarily short term, and cultures of continous cell lines which can be carried indefinitely by serial subculture. Here monkey kidney tissue culture will be taken as an example of a primary culture, and that of the HeLa cell as one of the many cell lines.†

Monkey kidney tissue culture. The capsule, connective tissue, and blood vessels in the pelvis are cut away from the kidney and discarded. With sharp scissors or two scalpels the tissue is cut into small pieces about 2 to 5 mm. in size. During this mincing process the tissue is kept moist with PBS, and washed frequently with larger quantities of PBS to remove as much blood as possible.

The minced tissue is transferred to a flask and 50 to 75 ml. of a warm (37° C.) 0.25 per cent solution of trypsin in PBS without calcium, and magnesium (i.e., solution (1) above), is added. The flask is incubated at 37° C. for 15 minutes, the supernatant trypsin poured off and discarded, and fresh trypsin is added, together with a Teflon-covered stirring bar. The flask is placed on a magnetic stirrer at room temperature, and the tissue suspension stirred for 10 minutes at a speed sufficient to keep the fragments of tissue in constant

motion without foaming. The supernatant trypsin, which now contains kidney cells, is decanted, fresh warm trypsin solution is added, and the process repeated.

Meanwhile the supernatant suspension of cells in trypsin is centrifuged at 700 rpm for 10 minutes to pack the cells. The supernatant is removed and discarded, and the cells are suspended in about 10 ml. of growth medium (0.5 per cent lactalbumin hydrolysate in Hank's BSS with 5 per cent calf serum). Each supernatant suspension of trypsin-released cells is treated in this way, and when the minced tissue has been completely digested, the suspensions of resuspended cells are pooled and filtered through three layers of gauze into a 250 ml. graduated centrifuge tube. The cell suspension is centrifuged at 700 rpm for 20 minutes, and the packed cell volume read.

The cells are now suspended in growth medium, using 300 ml. of medium for each ml. of packed cells. This suspension is transferred to the culture vessels. When these are test tubes, 16×125 mm., 0.5 ml. is added to each tube, and the tubes are incubated in a slanted rack so that the cells grow on the side of the tube. If prescription bottles are used, they must contain cell suspension to cover the flat side not more than 5 mm. deep. The uppermost side of the tube or bottle is marked so that, after examination, it can be returned to the incubator in the same position.

Observation of the progress of these cultures can be made with an ordinary compound microscope, using the 10× objective. The tubes or bottles are placed on the microscope stage with the cell layer uppermost. Since this drains the medium from the cells, prolonged observation should be avoided. When the desired cell population is reached, usually after five to seven days incubation at 37° C., the cultures are washed with warm Hank's BSS, and maintenance medium added, 1 ml. to each tube or corresponding amounts to bottle cultures. The maintenance medium, such as Medium 199 without serum, should be one that favors the growth of the virus under study. These cultures are now ready for inoculation with virus, or bottle cultures can be trypsinized as described below for HeLa cell cultures and more cultures prepared; these are often called secondary cultures.

HeLa cell culture. Stock cultures of HeLa cells are usually carried in prescription bottles and transfers made at five to seven day intervals when the cells have formed a confluent sheet on the side of the bottle. Cultures should not be kept longer than seven days because the cell population becomes too large, exhausting the medium and declining in viability.

For subcultures, the growth medium is removed and discarded, the cells washed with two changes of warm Hank's BSS, and sufficient 0.1 per cent trypsin in PBS without calcium or magnesium to cover the cells is added. After incubation at 37° C, for about five minutes, the cells float into suspension on slight agitation of the bottle. The cells are sedimented by centrifugation at 700 rpm for 10 minutes, the supernatant trypsin solution is discarded, and the cells are suspended in Eagle's medium, containing 10 per cent human serum by repeated pipetting. The cell suspension is counted in a hemocytometer, and diluted appropriately for use as an inoculum. Cultures in 16 × 125 mm. test tubes are inoculated with 50,000 cells in 1 ml., and 8 oz. prescription bottles, used for stock cultures, are seeded with 106 cells.

For virus propagation, the freshly seeded cultures

^{*}Many of the solutions and mediums used for tissue culture can be purchased as sterile stock solutions to be diluted in double-distilled water, or complete and ready to use. Sterile serums of many species are also available commercially.

[†]Such cell lines, and some primary tissue cultures such as monkey kidney, can be obtained commercially.

SEROLOGY

are incubated until sufficient cell growth has occurred, usually about four days. The growth medium is discarded and the cells washed three times with warm Hank's BSS, and maintenance medium added. The me-

dium may be Eagle's medium with 5 per cent chicken serum, or another of the mediums devised for this cell line which is best suited for growth of the virus.

29

Immunological Methods

The immunological or serological reactions serve to differentiate bacteria on the basis of their constituent antigens. Such immunological differences are usually, though not always, subordinate to the biochemical differentiation of species, and in general serve to subdivide species into immunological types or varieties. The immunological identification of an unknown microorganism is of considerable diagnostic utility and is frequently of very great value in epidemiological studies in tracing the source and dissemination of infection. Furthermore, serum may be tested against a known antigen to establish the presence of the homologous antibody and thus by inference the presence, immediate or past, of the microorganism or its products in the host, and therefore serves as an indirect diagnostic procedure. The specific neutralization of toxin by antitoxin in vivo serves to measure antibody in serum or the circulating antibody in the living host, and in the latter is a measure of antitoxic immunity. Of the in vitro immunological reactions, those of agglutination of a bacterial or other discrete antigen, precipitation of a soluble antigen, and complement fixation in the presence of soluble or discrete antigen are of general utility.

Titration of diphtheria antitoxin by the Römer method. The intradermal inoculation of diphtheria toxin in the rabbit produces local erythema, and central necrosis with larger doses, which may be used in the assay of toxin, and of toxin in the presence of antitoxin. The end point ordinarily taken is the smallest amount of toxin that, in a dose of 0.2 ml., will produce a zone of erythema 10 mm. in diameter 48 hours after inoculation. This is designated the minimal reacting dose or MRD, and the activity of a toxin may be measured as MRD per ml.

Such a titration measures the potency or toxicity of the toxin preparation, but not its combining power with respect to antitoxin. An expression of the activity of the toxin in the presence of antitoxin is the definition of the Lr dose. This is that amount of toxin which, when mixed with 1 unit of standard antitoxin, contains 1 MRD of unneutralized toxin. It will be clear that a toxin so standardized with respect to standard antitoxin can then be used to titrate an unknown antitoxin by using a constant amount of toxin mixed with serial dilutions

of the unknown antitoxin and testing of the mixtures for activity.

One application of this technique is the titration of the antitoxin content of the serum of persons, immunized, convalescent, or normal. This will be considered here since it illustrates all of the principles involved. In studies on human immunity the usual procedure is to titrate the serum against an amount of toxin which will just give the end point reaction when mixed with 0.002 units of standard antitoxin; this is commonly spoken of as titration at the 1/500th level.

Standardization of toxin at the 1/500th level. Toxins vary widely in potency and combining power, and no precise quantitative procedure may be given. The general model of the titration is as follows:

 Assume that a toxin whose L+ dose is known is available. Then the following preliminary titrations can be carried out:

(a) The standard antitoxin is diluted so that it contains 1 unit per ml.

(h) The toxin is diluted so that it contains 1 L+dose per ml.

(c) The toxin is titrated in dilutions of 1:100, 1:200, 1:300, up to 1:1000 against constant amounts of antitoxin, viz., 1 ml. of diluted antitoxin is mixed with 1 ml. of each toxin dilution, incubated as indicated below, 0.2 ml. of each inoculated intradermally in the rabbit, and the reaction read in 48 hours. This titration determines the Lr dose of toxin.

(d) Additional preliminary titration indicates the approximate amount of toxin required to just give the skin reaction in the presence of 1/500 unit of antitoxin. A more precise determination is carried out as follows:

 Prepare a dilution of the original toxin in sterile broth to contain exactly 100 Lr per ml. This is the so-called stock solution and is relatively stable if prepared from stabilized (aged) toxin.

(ii) Dilute 1 ml. of the stock solution to toxin with 99 ml. of buffer solution to give a solution containing | Lr per ml.

(iii) Prepare serial dilutions at intervals of 5 within the limits indicated by the above preliminary titration. Thus, if the end point is indicated as lying between 1:40 and 1:80, prepare 1:40, 1:45, 1:50, up to 1:80.

(iv) Mix 1 ml. of each dilution of toxin with 1 ml, of standard antitoxin diluted to contain 0.002 unit per ml. Incubate the mixtures for one hour at 37° C. and leave in the refrigerator overnight to allow ample time for the toxin-antitoxin reaction.

(v) Inject 0.2 ml. of each dilution mixture in-

Dilutions of	Patient's	Serum	for	Titration	Ωf	Antitovin	at	1/zooth	Level

0.1	49.9	1 in 500	î	$\tilde{1}/\tilde{1}$	

tradermally into the shaven skin of a rabbit (as many as 40 such inoculations may be made in a single animal without ill effects), and identify the sites of inoculation with dye.

(vi) Read at 48 hours, the end point being that dilution of toxin which produces a zone of erythema nearest to 10 mm. in diameter.

Titration of antitoxin at the 1/500th level. For the titration of antitoxin in serum proceed as follows:

- (1) Dilute the stock solution of toxin as indicated in the above standardization, i.e., so that 1 ml. contains sufficient toxin to give the skin reaction when mixed with 1 ml. of antitoxin containing 0.002 unit per ml. and inoculated in amounts of 0.2 ml.
- (2) Prepare dilutions of patient's serum, say, for illustrative purposes, of 1:10 and 1:500.
- (3) Mix 1 ml. of undiluted serum and 1 ml. of each of the dilutions with 1 ml. each of the diluted toxin, and in addition set up a control which contains 1 ml. of the diluted toxin and 1 ml. of standard antitoxin diluted to contain 0.002 unit.
- (4) Incubate, inoculate, and read as above.

Suppose the toxin mixed with the 1:500 and 1:10 dilutions of serum gives a skin reaction, but that mixed with the undiluted serum does not. It follows that the undiluted serum contains more than 1/500 unit of antitoxin per ml., but it contains less than 1/50 unit per ml. since it is not neutralized by the 1:10 dilution of serum. By varying the serum dilution, any fraction of a unit may be determined as indicated in the accompanying table.

The precipitin reaction. The precipitin reaction is the specific formation of a precipitate when a soluble antigen and its homologous antiserum are mixed. It is used for the identification of soluble antigens of bacterial extracts, such as pneumococcus polysaccharide and the polysaccharide and protein antigens of the streptococci, and is used for the immunological typing of a number of kinds of bacteria. It is also used for the identification of other protein antigens

as, for instance, the identification of bloodstains in forensic medicine.

In the precipitin test antiserum is used undiluted, or in very low dilution that avoids undesirable cross reactions, and is admixed with successive dilutions of the antigen. The titer of the antiserum is expressed as the highest dilution of antigen with which precipitation occurs. It is one of the most delicate and sensitive of the serological reactions; antiserums which will precipitate an antigen such as pneumococcus polysaccharide in dilutions as high as 1:1 to 1:5 million are not uncommon, and titers to serum antigens are frequently 1:10,000 to 1:100,000. The test is carried out as follows:

(1) Preparation of the antigen dilutions

- (a) Set up a series of small test tubes, such as Wassermann tubes, each with 0.5 ml. of saline solution.
- (b) To the first tube add 0.5 ml. of the antigen solution, mix well by blowing in and out of the pipette several times, and transfer 0.5 ml. of this solution to the second tube. The procedure is continued through as many tubes as the titer, or expected titer, of the serum indicates to give a series of dilutions of the antigen to 2ⁿ. If the original antigen solution is not diluted, these dilutions will be 1:2, 1:4, 1:8, etc., but it is more convenient to prepare a 1:100 dilution of the original antigen to begin with, thus giving dilutions of 1:100, 1:200, 1:400, up to 1:25,600.

(2) Procedure of the test

- (a) Distribute the antiserum in amounts of 0.1 ml. in a series of 5 × 50 mm. test tubes, as many as the dilution range to be observed requires.
- (b) Carefully layer 0.1 ml. of the antigen dilutions onto the antiserum, each of the serial dilutions in successive tubes, so that the juncture between the two is clear and sharp.
- (c) Incubate at 37° C. for two hours, examining at 30-minute intervals for the formation of precipitate at the juncture of antiserum and antigen. This the precipitin ring test.
- (d) Shake the tubes to mix thoroughly the antiserum and antigen and store overnight in the refrigerator.
- (e) Next day the precipitate will have settled out

and can be read by gentle agitation of the tubes.

(f) It is essential that controls of antigen plus saline, and antiserum plus saline, be included, and these should show no precipitate.

The precipitin test may also be carried out in capillary tubes to conserve antiserum, and to utilize the relatively small quantities of antigen available in bacterial extracts as in the typing of streptococci.

Flocculation tests. The so-called flocculation tests developed for the serological diagnosis of syphilis are related in a sense to the precipitin reaction, and the Kahn test is typical of these. The Kahn antigen is a lipid fraction of heart muscle soluble in alcohol but insoluble in acetone, and contains added cholesterol. When this antigen is mixed with saline in certain proportions floccules appear, and the antigen is titrated to determine the smallest amount of saline which, when added to 1.0 ml. of antigen, produces aggregates which completely disperse upon the addition of more saline. Syphilitic serum has the property of preventing this dispersion. The test is based on the mixture of constant amounts of serum with varying concentrations of antigen which are thoroughly mixed by shaking in a shaking machine, and the addition of saline. The test is set up according to the accompanying protocol and read immediately and again 10 minutes after the addition of saline. A positive reaction is indicated by the presence of floccules in the mixture.

Agglutination. Bacteria, and other particulate antigens, aggregate in clumps in the presence of homologous santiserum and are

said to be agglutinated. The agglutination reaction is useful in the serological identification of bacteria, especially those of the group of enteric bacilli such as the Salmonella and dysentery bacilli. It is also the immunological reaction made use of, in conjunction with agglutinin absorption, in the antigenic analysis of bacteria.

The agglutination reaction differs from the precipitin reaction in that the antiserum rather than the antigen is diluted, and the antibody titer of the antiserum is expressed as the highest dilution in which a constant amount of bacterial antigen is agglutinated. Agglutinating antiserums commonly show titers ranging from 1:1000 to 1:10,000 and occasionally may reach titers as high as 1:50,000 to 1:100,000, though this is rare. The agglutination of bacteria may be observed either microscopically or macroscopically; the former is generally used for typing purposes, the latter in the titration of antibody.

The microscopic agglutination test. In the microscopic agglutination test either only a few, e.g., two or three, dilutions of antiserum are used, or more commonly, a single dilution is used which preliminary titration has indicated will produce a rapid and complete agglutination with minimal cross reactions. This last allows the use of a single rapid test for typing and certain diagnostic purposes. The test is carried out as follows:

(1) Place a loopful of saline solution on a clean cover slip, and with the straight inoculating wire add

Protocol of Agglutinin Titration

	SERUM	DILUTION		AGGLUTININ TITRATION						
	SERUM (ML.)	SALINE (ML.)	DILUTION	TUBE NUMBER	SALINE (ML.)	SERUM (ML.)	ANTIGEN (ML.)	FINAL DILUTION		
A	0.1 of undiluted serum	4.9	1:50	1 2 3	0 0.25 0.40	0.50 0.25 0.10	0.5 0.5 0.5	1:100 1:200 1:500		
В	0.5 of dilution A	4.5	1:500	4 5 6	0 0.25 0.40	0.50 0.25 0.10	0.5 0.5 0.5	1:1000 1:2000 1:5000		
	0			Control	0.50	0	0.5			

a small amount of bacterial growth. The suspension should be faintly turbid, and when this point is reached, the needle is flamed and then used to stir the drop to a homogeneous turbidity.

(2) Place a loopful of diluted antiserum beside the drop of bacterial suspension. Traces of serum remaining on the loop are, of course, removed by flaming.

- (3) With the inoculating needle mix the two thoroughly. Note that this produces and additional dilution of the antiserum, and the final dilution is approximately twice the original dilution.
- (4) Mount the cover slip on a hollow ground slide with petroleum jelly as in making a hanging drop preparation. No special incubation is necessary, and in a few minutes to an hour at room temperature agglutination occurs.
- (5) The preparation may be examined under the low power objective for a curdled appearance or under high power or oil immersion objectives for direct observation of the agglutinated bacteria. False clumping may occur and is distinguished from true agglutination in that in the latter all of the bacteria are gathered in large clumps with none about the edges of the drop, but false clumping occurs in small aggregates about foreign particles and around the edge of the drop.

Macroscopic agglutination. The titration of agglutinin is carried out in a manner similar to the titration of precipitin except, as noted above, with varying amounts of serum in the presence of a constant amount of antigen.

- (1) PREPARATION OF ANTIGEN
 - (a) Inoculate an agar slant culture with the bacteria to be used as antigen, spreading the inoculum over the entire surface of the slant.
 - (b) After 18 hours' incubation run about 2 ml. of saline solution on the agar slant culture. The saline may contain 0.5 per cent formalin if a formalinized antigen is to be used.
 - (c) Rub up the bacterial growth with an inoculating needle or loop to give a uniform suspension of the bacteria in the saline.
 - (d) With flamed forceps remove a small piece of cotton from the bottom (sterile) part of the cotton plug of the culture tube and drop it into the saline suspension.
 - (e) With a sterile pipette push the piece of cotton to the bottom of the saline, taking care to leave the cotton over the pipette opening.
 - (f) Draw up the bacterial suspension into the pipette through the cotton, which serves to

filter out coarse particles, and add this suspension slowly to the proper turbidity to whatever volume of saline solution is required for the titrations to be undertaken. (A single agar slant culture will make 100 to 300 ml. of antigen, depending on the amount of bacterial growth and the density of the final antigen.) The turbidity of the final antigen such that, when diluted with an equal volume of saline, it will be lightly turbid in the test tubes used for the titration. The precise turbidity is dependent upon the kind of antigen and antibody and on the personal preference of the worker.

- (2) PREPARATION OF SERUM DILUTIONS
 - (a) Serum may be diluted in essentially the same manner as antigen is diluted in the precipitin test, and the dilution is carried out in 10×75 mm. test tubes used for the titration of agglutinin since the antigen is added directly to the diluted serum. A common procedure is to set up a series of saline blanks, the first containing 0.9 ml. and the remainder 0.5 ml. The first dilution is 1:10, made by adding 0.1 ml. of serum to the 0.9 ml. blank; the second and subsequent dilutions are made by transferring 0.5 ml. portions of each preceding dilution. This gives dilutions of 2^n , i.e., 1:10, 1:20, 1:40, . . . etc.
 - (b) The above method is the one of choice when only a very few titrations are to be run but is laborious and time-consuming if there are many titrations. An alternative, more efficient procedure less subject to dilution error arising from carrying over excess serum in the pipette, since so few pipettes are used that a fresh one for each dilution is practical, is shown in the above table. In this method only one direct dilution is made for each three final serum dilutions, and the dilutions closely approximate 2ⁿ.
- (3) PROCEDURE OF THE TEST
 - (a) To each of the series of tubes containing 0.5 ml. each of the several serum dilutions, add 0.5 ml. of antigen suspension and mix by gentle agitation. Note that this doubles the serum dilution, and the final dilutions are 1:20, 1:40, 1:80, . . . etc., when made by the first method; the final dilutions in the second method are given in the table.
 - (b) The method of incubation is variable, depending

upon the particular system being titrated, and the following methods are common:

- (i) Incubate at 37° or 55° C. for two hours, read and store overnight at room temperature or in the refrigerator, and read again.
- (ii) Incubate at 37° C. overnight and read the following morning.
- (c) The agglutinated bacteria form clumps of precipitate in the bottom of the tubes and are read in a cross light to give a Tyndall effect by gently agitating the tubes individually to swirl the agglutinated bacteria up into the supernatant. The character of the agglutinated bacteria differs in different circumstances; the H agglutination of Salmonella. for instance, is flocculent, while the O agglutination is finely granular. Some workers record degrees of agglutination from + or barely perceptible partial agglutination to ++++ of complete agglutination with a clear supernatant, while others simply record the presence or absence of agglutination with a single + or - sign. The agglutinin titer of the antiserum is the highest dilution in which definite agglutination occurs.

Complement fixation. The complement fixation test is based on the observation that complement, a heat-labile constituent of normal serum, combines with an antigenantibody complex and is said to be fixed. Since this fixation produces no visible change, a hemolytic system, consisting of sheep erythrocytes and anti-sheep cell hemolysin, is added. If the complement is free, i.e., has not been fixed, and inferentially the original union of antigen and antibody has not occurred, the erythrocyte-hemolysin complex combines with the complement. and visible lysis of the red cells occurs. Conversely, if the erythrocytes are not lysed, the test antigen-antibody system has combined and fixed the complement, leaving none for hemolysis. This complement fixation test is most often applied in the serodiagnosis of syphilis and virus and rickettsial infections. Bacterial antigens fix complement readily.

The following reagents are required:

- (1) The antigen-antibody system to be tested, either component of which may be unknown.
- (2) Anti-sheep erythrocyte hemolysin, prepared by the immunization of rabbits with sheep red cells.
- (3) A 2 per cent (by volume of packed cells following centrifugation) suspension of washed sheep erythrocytes in saline.
- (4) A source of complement, practically always fresh guinea pig serum.

Titration of reagents. Since the test is necessarily quantitative with respect to the relative proportions of the various components, the activity of these must be titrated prior to the actual test. These preliminary titrations include:

- (1) The titration of hemolysin which is carried out by varying the amount of hemolysin in the presence of constant amounts of sheep erythrocytes and complement, the last in amounts more than necessary for complete lysis. This titration is carried out as indicated in the accompanying protocol. The smallest amount, i.e., highest dilution, of hemolysin required to bring about complete lysis is the hemolytic unit. In the final test two units in a volume of 0.5 ml. are used in each tube and on the basis of this titration the hemolysin is diluted to contain four units per ml.
- (2) The complement of fresh guinea pig serum is similarly titrated, using variable amounts of complement in combination with constant amounts of erythrocytes and hemolysin as shown in the accompanying protocol, and the unit of complement is defined. The "exact unit" is the smallest amount that gives complete hemolysis, and the next larger amount, i.e., in the adjacent tube, is the "full unit." In the complement fixation test two full units in a volume of 1.0 ml. are used in each tube. The reason for the excess amount is

^{*}Control must be negative.

that some complementary activity is lost during the time allowed for fixation; even if no fixation occurs, the test is sufficiently sensitive even with this slight excess.

(3) Certain properties of the antigen are pertinent to the test and must also be determined by preliminary titration. These properties include anticomplementary activity, i.e., inhibition of the action of complement, hemolytic activity, and binding power for complement. The titration of these is shown in the accompanying protocol. In general, the binding power of the antigen should be at least 10 times its anticomplementary action, and in the final test not more than one third of the amount of antigen found to be anticomplementary may be

used. It is self-evident that the antigen must not lyse red cells in the concentrations used in the test.

Procedure of the test

- (1) Inactivate the test serum, i.e., destroy any traces of of complement in it, by heating to 56° C. for 15 to 20 minutes; dilute 1:5 and distribute in three 15 × 100 mm. test tubes as indicated in the accompanying protocol. Bring the total volume in tubes 2 and 3 to 0.5 ml. by adding 0.25 and 0.375 ml. of saline respectively.
- (2) Add 0.5 ml. of antigen, diluted to contain 20 complement-fixing units per ml. to each tube.
- (3) Let the mixture stand at room temperature for 10 minutes.

SC serum control-should show complete hemolysis.

AC antigen control—should give complete hemolysis.

HC hemolytic system control—should give complete hemolysis.

EC erythrocyte control—should give no hemolysis.

- (4) Add 1.0 ml. of complement, diluted to contain two full units per ml., to each tube.
- (5) The mixture may be incubated in a water bath at 37° C. for one hour, or stored in the refrigerator overnight and warmed in the water bath for 10 to 15 minutes before proceeding with the test the following day. This time interval is allowed for fixation of the complement by the antigen-antibody complex, and the later method is referred to as "icebox fixation."
- (6) Add 0.5 ml. of hemolysin diluted to contain four hemolytic units per ml. to each tube.
- (7) Add 0.5 ml. of a 2 per cent suspension of washed sheep erythrocytes to each tube.
- (8) The appropriate controls of the serum, antigen, hemolytic system, and erythrocyte suspension are indicated in the protocol and must be included.
- (9) Incubate in a water bath at 37° C. for 15 to 60 minutes.
- (10) Read the hemolysis as complete (++++), partial (+++, ++, +, ±), or negative.

Chapter Three

THE PHYSICAL AND CHEMICAL STRUCTURE OF MICROORGANISMS

One of the most striking aspects of the morphological consideration of microorganisms is their extremely small size. This order of size is such that they are most conveniently measured in the units of the micron $(\mu = 10^{-3} \text{ millimeters})$ and the millimicron $(m\mu = 10^{-6})$ millimeters). The proper, those capable of independent metabolic existence in that they are cultivable on lifeless nutrient mediums, range in size from that of the large bacilli,* such as Bacillus anthracis, with dimensions of 1.0 to 1.3 \times 3 to 10 μ , to minute forms such as Pasteurella tularensis measuring 0.2×0.2 to 0.7μ and microorganisms of the pleuropneumonia group in which viable elements as small as 175 m μ are demonstrable.

The rickettsiae and viruses, characterized by their inability to proliferate apart from a living host cell, form a continuous series of even smaller forms, running through and beyond the limits of optical resolution, commonly taken to be 200 mµ but in practice about 250 m μ . The rickettsiae resemble the small bacteria, having dimensions of 0.2×0.5 to 1.5 μ , and the poxviruses, whose elements measure 200 to 350 m μ , also overlap the smallest bacteria. From this maximum, the viral agents range down to nearly macromolecular dimensions such as 25 m μ for poliomyelitis virus and 22 m μ for foot-and-mouth disease virus, while the egg albumin molecule, for example, measures 2.5×10 m μ . The relative size of representative micoorganisms is illustrated in Figure 3.

The range in size among individual bacterial cells of the same species differs from one species to another, being greatest in the bacillary forms and least in the spherical types. Excluding filamentous and swollen forms that may be produced under appropriate conditions and are usually regarded as abnormal, the maximum difference in size between mature individual cells is about fourfold to fivefold.

The structure and physiological processes of a living organism are intimately associated with, and in fact are a function of, its size. 109 While substantially the same mechanisms are functional in terrestrial mammals from the elephant (400 kg.) to the pigmy shrew (4 gm.), a mammal smaller than the very small rodents cannot exist because it could not assimilate and metabolize nutriment rapidly enough to supply the energy it requires. Similarly, the rate of oxygen diffusion in insect tracheas limits the size range of organisms using this respiratory mechanism between a maximum represented by some tropical forms 5 to 8 cm. in length and the minimum of small mites 0.2 mm. long.

The lymphocyte, one of the smallest mammalian cells, with a diameter of 10μ and a volume of $524 \mu^3$, is many times larger than B. anthracis with a maximum volume of $22 \mu^3$, and the minimum volume of $0.004 \mu^3$ of Past. tularensis. The last appears to represent the minimum size that allows the

^{*}Excluding the often quoted but exceptional case of *Bacillus biitschlii*, found in the cockroach intestine, and reported to be as large as $0.6 \times 80 \mu$.

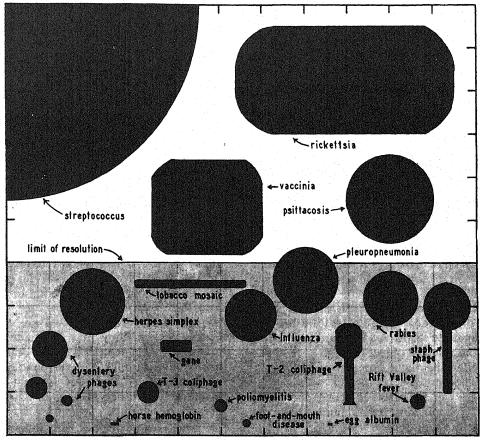

Figure 3. Diagrammatic representation of the relative size of representative microorganisms. The pips are at intervals corresponding to 100μ , and the small squares of the grid to $10~m\mu$. The microorganisms in the shaded portion are those whose size is below the limits of resolution of the light microscope.

degree of organization necessary to independent metabolism in that the smaller agents, the viruses, are obligate intracellular parasites.

The size range of the obligate parasites overlaps that of the metabolically independent microorganisms in that the larger forms, such as Coxiella burnetii having a volume of $0.02 \ \mu^3$ and the largest viruses, such as vaccinia virus with a volume of $0.008 \ \mu^3$, are larger than Past. tularensis and other extremely small bacteria. But smaller forms, running in continuous series to the apparent minimum of the volume of $0.00005 \ \mu^3$ of foot-and-mouth disease virus, can at best contain only relatively few protein molecules.

While metabolic processes on a molecular level need not differ significantly between large and small physiological units, it may be anticipated that the relative lack of cellular structure may result in unique characteristics of the minute forms. This has proved to be true, in part because these minute forms do not appear to be closely restricted to the hereditary mechanisms, processes of proliferation, etc., to which the more elaborately organized unicellular and multicellular organisms are limited, and in part because of the special circumstances of their macromolecular environment. The uniqueness of the microorganisms is more apparent than real, then, in that their unusual properties and behavior represent an extension of, rather than a contrast with, the patterns of basic biological phenomena.

MICROSCOPY24

A consideration of the technical limitations and advantages of the various methods available for the demonstration of the shape and structure of microorganisms is an essential preliminary to a consideration of the morphology of these forms. In general, these methods are of two kinds, *viz.*, those utilizing light, both visible and ultraviolet, and that making use of a focused beam of electrons.

compound microscope. With The ordinary microscope, objects are viewed by transmitted light, i.e., the object is interposed between the source of light and the eve or photographic plate. In order to be seen and delineated (resolved) the object must be sufficiently large to cast a shadow, and the critical size is approximately half the wave length of the light used. The highest numerical aperture that is practical in the objective lens is 1.4, and this permits resolution of objects down to the critical size. The limit of resolution is obviously a function of the wave length of light used. Thus in the range of 5000 Å (500 m μ), or blue light, to 5500 Å (550 m μ), or yellow light, the smallest object that can be resolved is a sphere having a diameter of 250 to 275 mu. Theoretically an object as small as 200 m μ can be resolved using deep blue light at 400 m μ wave length, but the practical limit is less than this.

Resolving power may be appreciably extended by the use of light in the ultraviolet region; assuming a wave length of 250 m μ , a sphere 125 m μ in diameter may be resolved. Quartz lenses are, of course, required.

The darkfield microscope. In the darkfield microscope reflected rather than transmitted light is used, taking advantage of the familiar Tyndall effect perhaps most commonly seen in the appearance of particles of dust in a shaft of sunlight in a darkened room. The usual compound microscope may be used by substituting a darkfield condenser, which lights the object from the side, for the ordinary substage condenser. Relatively large amounts of light are required, and oil is placed between the top of the condenser and the slide to reduce loss at these interfaces.

The object appears brilliantly lighted against a dark background. There is an illusion of increased resolution in that extremely small objects appear as bright points of light in contrast with the minute shadows cast in transmitted light, but, in fact, resolution is not increased beyond the critical limits noted above. Thus the darkfield micro-

scope has not contributed appreciably to bacterial cytology other than with regard to certain aspects of the activity of flagella. It has, however, very considerable utility in the demonstration of very slender microorganisms, especially spirochetes, as in exudate from a syphilitic chancre or leptospira in the blood from cases of leptospirosis.

The phase microscope. 9, 83 Light passing through an object of different thickness or refractive index from that of the surrounding fluid is scattered, with the result that it is out of phase and reduced in amplitude, i.e., the distance from the crest to the trough of the light wave is reduced. Differences in amplitude are visible and allow the observation of the object as a relatively faint shadow against its background, and bacteria may be so observed in the living unstained state, usually in a wet preparation.

While differences in phase are not ordinarily visible, they may be made so by treating the light scattered by the object and that coming through the surrounding fluid independently so that they interact, either to interfere with one another to darken the image or to reinforce one another to brighten it. This is accomplished with the ordinary microscope by restricting the incident light to an annular beam by means of an annular diaphragm at the lower focal plane of the condenser and the insertion of a corresponding annulus or diffraction plate at the back focal plane of the objective lens. The microscope so modified is a phase microscope and may be either bright or dark phase.

Phase contrast microscopy has been particularly useful in the study of structures in the living cell, unmodified by the artifacts inherent in the processes of fixing and staining. By increasing contrast, it gives greatly improved resolution, for example, allowing the demonstration of bacteria in unstained tissue sections that are not resolved by the bright- or darkfield microscopes because of the relatively great diffraction and reflection of the tissue elements. The phase microscope is, however, subject to the same limits in ultimate resolving power as other forms of the microscope using visible or ultraviolet light.

The electron microscope. 49, 120 The electron microscope operates on a different principle from that of the optical microscopes in that a stream of electrons is used rather than a beam of light. The electron

beam is focused by magnetic "lenses" and the interposed object intercepts the beam to cast a shadow which is recorded on a photographic plate to give an electron micrograph. The theoretical resolving power of the electron beam is about 100,000 times that of visible light, but this limit is not reached in practice because of defects in the magnetic focusing corresponding to chromatic and spherical aberration in optical systems. Nevertheless, remarkable resolution is possible at 10,000 to 50,000 diameters and, because of the small aperture used, the depth of focus is considerably greater than that obtainable with the 1.4 mm. objective.

The technique of shadow-casting with heavy metals vaporized under high vacuum and deposited at an angle on the preparation was developed by Williams and Wyckoff in 1946. The metal film is opaque to electrons, and the resulting electron micrograph has a brilliantly lighted three-dimensional

appearance. Subsequently the technique of negative staining with phosphotungstate, analogous to the negative staining techniques of light microscopy, was introduced. It has been particularly useful in the elucidation of the structure of virus particles since it shows fine structures not apparent in thin sections of particles embedded in osmic acid-methylacrylate.

Application of electron microscopy to microorganisms has made it possible to see details of structures lying at the limits of optical resolution and to determine directly the size and shape of small viruses previously studied only by indirect methods such as sedimentation and filtration. The results of electron microscopy must be interpreted with some caution because specimens can be examined only as dead dry material because of the high vacuum required and are subject to the very considerable distortion of drying.

The Morphology of Bacteria 14, 105, 107

The morphology of bacteria may be considered under two general heads: that of individual cells and groups of cells as observed under high magnifications, and that of bacterial colonies developing on solid mediums and consisting of very large numbers of cells that are visible to the naked eye. In the first instance differences in shape and certain structural details as well as size are characteristic of at least the main groups of bacteria and provide the primary basis for their systematic study. Similarly, the masses of cells represented in the bacterial colony also have characteristics such as size, consistency, texture, and color that have differential value though not the fundamental significance of cellular morphology.

THE BACTERIAL CELL

Shape. The most obvious difference among bacteria is their shape, and three general morphological types are clearly evident. These are the spherical form or coccus, the rod-shaped form or bacillus, and the spiral forms, the various subtypes of which are the vibrio, spirillum, and spirochete.

Coccus. The spherical bacteria are by

far the most homogeneous of the bacteria with respect to size and, in general, have a diameter of 0.8 to 1.0 μ , although smaller varieties, 0.4 to 0.8 μ in diameter, have been described. There is some small deviation from the spherical form among bacteria grouped as cocci. The pneumococcus, for example, has a lanceolate shape, slightly elongated with one end more pointed than the other, and the gonococcus and meningococcus tend to a coffee bean shape. Other slightly elongated forms are referred to as coccobacilli, and the line of demarcation is not precise.

Morphological subtypes of the cocci are differentiated on the basis of the arrangement of the individual cells with respect to one another. This is a consequence of two factors, one the plane or planes in which cell division occurs, and the other the tendency of daughter cells to remain superficially attached or close to one another after division is complete.³⁹

Those cocci which separate completely after cell division, regardless of the plane of division, appear singly, and scattered at random over the microscopic field are called *micrococcus*. When there is a slight tendency for daughter cells to remain attached, and cell division occurs in only one plane, the

cocci tend to occur as pairs, diplococcus, but the paired cells are intermingled with individual cells. Some kinds of diplococci are slightly elongated and are paired with the long axes parallel. In the case of the coffee bean-shaped gonococcus and meningococcus noted before, the paired cells have the convex sides adjacent. When the tendency to remain attached is more marked, the result is chains of cells, streptococcus, consisting of four to ten or a dozen cells that often have the appearance of diplococci attached end to end.

When there is a marked tendency of daughter cells to remain adjacent to one another coupled with cell division in two or more planes, the cocci occur as irregular groups, staphylococcus, which are often quite large. When observed in the usual stained preparation, staphylococci appear to consist of sheets of cells, i.e., only one cell thick, but on examination in a wet mount are seen to consist of irregular, grape-like clusters. The former would result from cell division occurring in only two planes, and the latter from division in three planes, but it is probable that the sheets of cells are, for the most part, an artifact resulting from the preparation of the smear. When the tendency to remain together is less marked, the cocci are found in tetrads or groups of four cells and in cubical packets of eight cells. There is no casual name for these smaller aggregates, but they are characteristic of some genera, such as Sarcina.

Separation of these subtypes of coccus on a morphological basis is not completely sharp. Thus, diplococci occur admixed with single cells, streptococcus chains are interspersed with paired and single cells, and single and paired cells, as well as an occasional chain of four cocci, are found in stained smears of staphylococci. It is obvious that these groupings can be broken up to a greater or lesser extent in preparing the bacterial suspension for examination and that the occurrence of typical groupings is not absolute, but the consequence of only a tendency to remain adjacent. In practice, though, the characteristic morphological groups are usually found without difficulty and are most consistently observed among the staphylococci.

Bacillus. The cocci merge into the rodshaped bacteria through connecting links such as the lanceolate coccus and coccobacillus noted above. In turn, the rod-shaped or bacillary form is a collective term that embraces a variety of morphological subtypes.

The morphology of individual rod-shaped bacteria differs considerably between genera and even species. Not only is there variation in size, but the shape of the individual cell differs, sometimes markedly. Some are long and slender while others may be short and thick; the sides may be more or less parallel to one another, or the cell may be thicker in the center and taper toward the ends to give the form known as the fusiform bacillus.

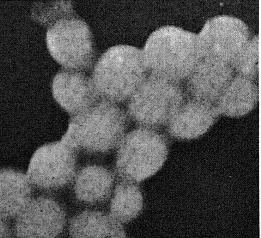

Figure 4. Electron micrographs of gold-shadow-cast preparations of *Bacillus subtilis* and *Staphylococcus aureus*. The shadow-cast preparation illustrates particularly well the occurrence of staphylococci in clusters of attached cells. The cap at the ends of the bacillus and a single flagellum are shown. (Lilly Research Laboratories.)

SPIROCHETES 41

Similarly, the ends of the cells may be square and cut off sharply, or even give the appearance of a slight concavity, while the ends of other cells are rounded. These variables can occur in a number of combinations to give a considerable heterogeneity in the bacillary form. A given shape is, however, relatively constant within a species under standard conditions of growth, though the length-width ratio may vary, owing in large part to elongation of individual cells prior to cell division.

Like the cocci, some of the bacillary forms assume characteristic groupings, but these are a consequence of postfission movements, for the plane varies rarely if at all from that vertical to the long axis. There is a tendency of the cells to remain attached, or closely adjacent, after cell division in some kinds of bacilli; it is marked in some forms, notably the spore-forming aerobic organisms of the genus Bacillus, and may be enhanced under appropriate conditions of growth. When this occurs, it results in the formation of chains of cells, the *streptobacillus* morphological type.

The postfission movements of bacilli are of two general kinds. The one, known as slipping, consists of a sliding movement of the cells against one another with the long axes parallel to give groups of cells with a palisade-like appearance. This appears to be a consequence of space limitations interfering with continued extension of growth in a longitudinal axis. In the other kind of movement, snapping, after division the daughter cells bend sharply with respect to one another to an acute angle to give a V-shaped appearance. When this kind of movement is associated with a tendency to remain attached end to end, chains of cells resembling a split-rail fence result.40

While to a certain extent characteristic, the groupings assumed by the rod-shaped bacteria have only minor differential significance in contrast to the cocci among which they make possible morphological subtypes of generic status.

The spiral forms. The third main morphological type of bacteria is made up of the spiral forms which may be regarded as bacillary forms twisted in the form of a helix. Again, forms intermediate on a morphological, though not necessarily phylogenetic, basis occur as the curved rods. These range from the occasionally curved

coliform bacilli to those forms whose curvature is sufficiently consistent to have differential significance in the definition of the genus Vibrio. Whether the vibrios are truly transitional forms linking the slender bacilli with the spiral microorganisms is questionable, but their occasional end-to-end grouping in which the direction of curvature of the individual cells alternates superficially resembles the spiral form.

The spiral bacteria, which if straightened out would be long slender bacilli, are of two general kinds, the one in which the spiral is rigid, the genus Spirillum, and the other in which it is flexible. Among the latter, a further differentiation is made on the tightness of the coiling. The tightly coiled forms include several genera which are differentiated by finer morphological criteria. These include differentiation of an outer sheath, a central filament about which the protoplasm is coiled, etc.; such structural details are illustrated in the accompanying electron micrograph.

One of these is the genus Treponema which includes pathogenic forms, notably the causative agent of syphilis and related diseases, together with a wide variety of nonpathogenic but parasitic forms such as those making up a part of the normal flora of the mouth. Still another form, distin-

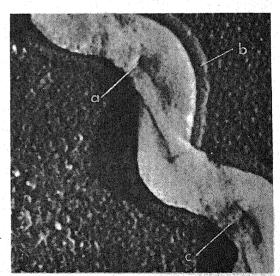

Figure 5. Electron micrograph of a chromium-shadow-cast preparation of Leptospira icterohaem-orrhagiae. The axial filament is separated from the protoplasmic spiral by a narrow space at (a) and is more closely approximated at (c). The sheath is shown at $(b) \times 125,000$. (Simpson and White.⁹²)

guished by sharp, hook-like bends at the ends of the cell, makes up the genus Leptospira, a causative agent of infectious jaundice.

Much less tightly coiled spiral forms which have, in fact, the appearance of extremely long, slender, undulating bacillary forms, make up the third morphological subtype. This includes both parasitic and pathogenic forms, the latter causing the louse- and tick-borne relapsing fevers in man and related diseases in certain fowl, and they are grouped under the genus Borrelia.

Taken together, the spiral forms are casually referred to as the spirochetes. The emphasis on morphological criteria for purposes of differentiation and definition of genera is a consequence of their failure, with the exception of Leptospira, to grow on laboratory mediums and, therefore, a complete ignorance of differential physiological activity that provides much of the basis for the characterization of other bacteria.

Involution forms. The great majority of bacteria are relatively constant in shape and size in young cultures actively growing under favorable conditions. In older cul-

tures in which many of the cells are dead or dying, the cell structure breaks down and aberrant forms appear. These include balloon-like structures, Y-shaped bacillary forms, cells containing large amounts of granular material, and the like. These are degenerative forms or involution forms and presumably result from breakdown of the mechanisms of selective permeability with imbibition of water, autolysis of cell structures by the action of proteolytic and other intracellular enzymes, etc. Some workers have attached significance to bizarre forms found in older cultures, regarding them as representative of an orderly sequence of morphological types indicative of a complex life cycle.

Aberrant forms of bacteria may also be p oduced by growing them under somewhat adverse conditions, such as higher than optimum temperatures, in the presence of relatively large concentrations of inorganic salts,³⁷ and sublethal concentrations of antibacterial substances. In the case of the last, the antibacterial activity may be largely growth-inhibiting rather than bactericidal, one result of which may be an inhibition of

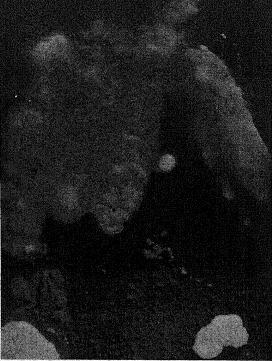

Figure 6. Electron micrographs of gold-shadow-cast *Bacterium coli* from old cultures. One intact cell is present, and the remainder show the granulation of dead and disintegrating cells. (Lilly Research Laboratories.)

the processes of cell division rather than of synthesis of cell substance, so that giant cocci, etc., develop in such cultures.

THE STRUCTURE OF BACTERIAL CELLS

The total physiological activity of the bacteria is, in many respects, so closely similar to that of the larger forms, that the assumption of at least some common mechanisms on a molecular or macromolecular level is more than a working hypothesis. While it is obvious from even cursory examination that the bacterial cell is discontinuous and therefore has structure, at the same time considerations of size make it equally clear that its structural elements need not be, and in fact in some instances perhaps cannot be, small scale replicas of those found in larger cells. The problem becomes, then, one of elucidation of the nature of subcellular elements and of their relation to the physiological functions of the cell.

The reference point is necessarily the living cell, and the information obtained by direct observation is subject to the limits imposed by the degree of optical resolution possible with visible, or ultraviolet, light. This basic information is supplemented and complemented by studies on killed cells treated with stains and other cytochemical reagents and/or subjected to observation

under the high magnifications obtainable in the electron microscope. Such supplementary information must be treated with due reservation because of artifacts resulting from fixing, drying, and other preparative procedures.

For purposes of discussion the bacterial cell structures may be divided into two groups, those structures which are external to the cell proper and those which occur within the cell.

EXTERNAL STRUCTURES

Two kinds of structures are external to the bacterial cells, the flagella or organs of locomotion and the capsular material or slime layer surrounding the cell. Neither is essential to the continued existence of the cell. A bacterium may be deprived of its flagella, as by mechanical shaking, or of its capsule by enzymatic digestion, without inhibition of growth or metabolic functions.

Flagella. $^{56, 101, 116}$ The bacterial flagellum is a long filamentous appendage originating in a spherical body, or basal granule, about $100 \text{ m}\mu$ in diameter and located in or just inside the cell wall. It is not clear whether these bodies correspond to the blepharoplasts of ciliated protozoa, but flagella are distinct from, though analogous to, cilia.

The flagellum is usually 12 to 15 m μ in diameter, without taper, and of variable

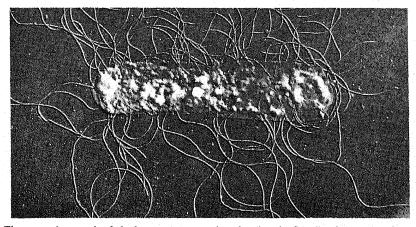

Figure 7. Electron micrograph of shadow-cast preparation showing the flagella of *Proteus vulgaris*. The bacteria were grown to the swarming stage on agar, refrigerated at 5° C. for 16 to 20 hours, floated off in 5 per cent formalin, and washed twice before mounting on collodioh. The preparation is very transparent and flattens completely so that certain of the internal structures are demonstrable by shadowing. The origin of the flagella in small, spherical bodies about 100 m μ in diameter and remarkably uniform in size is clearly shown. (van Iterson.)

length, in an extreme range of 1 to 70 μ , but ordinarily 15 to 25 μ . In the living cell it is coiled in the form of a cylindrical helix, but in dried preparations the third dimension is minimized and it appears as a wavy filament. Because of its length the flagellum is demonstrable occasionally in the living cell by phase contrast microscopy and more readily with the darkfield microscope. In mordanted stained preparations, the stain is deposited on the flagellum to make it sufficiently thick that it may be observed with the conventional microscope and is, of course, readily seen in electron micrographs.

Flagella occur most commonly, although not exclusively, among the rod-shaped bacteria. They may be attached either at or near the poles of the cell or distributed over the rest of the cell surface with a tendency for the poles to remain bare, and their location and number are relatively constant within bacterial species. The classification of bacteria with respect to the occurrence of flagella is the early one of Messea. According to this, the bacteria having a single polar flagellum are designated monotrichous. those having two or more flagella at one end of the cell lophotrichous, those having tufts of flagella at both ends of the cell amphitrichous, and those having flagella, usually eight to 12, distributed over the cell surface are peritrichous.56

The rate of movement of motile bacteria is often surprisingly rapid. For example, the motile enteric bacilli, such as the typhoid, coliform, and related bacteria, have been found to average speeds of 25 to 30 μ per

second and the cholera vibrio to move as fast as 55 μ per second. These rates are comparable with automobile speeds of 40 to 80 miles per hour.

The flagellar substance is antigenically distinct from that of the cell, and antibody to it is specific. The function of flagella in motility is seriously interfered with in the presence of specific antibody, and the organisms are immobilized because of agglutination of the flagella.⁶⁷ This is the basis of the "immobilization test" which has considerable serodiagnostic utility in diseases such as syphilis.

Flagella also differ in chemical composition from the cell substance proper. They may be removed from the cell by vigorous shaking and separated by differential centrifugation. They are built up as linear polymers of small protein molecules which are depolymerized in weak acid (0.05 M CHI) to give a clear colorless solution and an acidinsoluble fraction rich in phosphorus and carbohydrate. The protein may be repolymerized in strong salt (e.g., 50-60 per cent $(NH_2)_2$ SO₄) solutions to give an opaque viscous solution. In this form it behaves like a solution of long thin protein molecules, and is found in electron micrographs to consist of small rod-like particles resembling fragmented flagella. Its amino acid composition is characteristic, and no histidine, tryptophan, hydroxyproline, or cystine is found in detectable amounts. The chemical composition appears to be the same in different genera of bacteria such as Proteus and Bacillus.

X-ray diffraction studies have shown

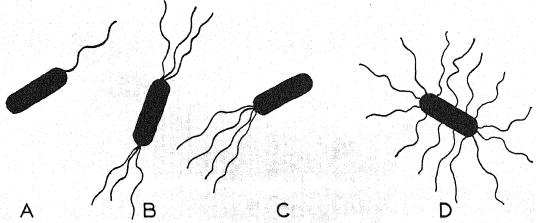

Figure 8. Position of flagella on the bacterial cell. A, monotrichous; B, amphitrichous; C, lophotrichous; D, peritrichous.

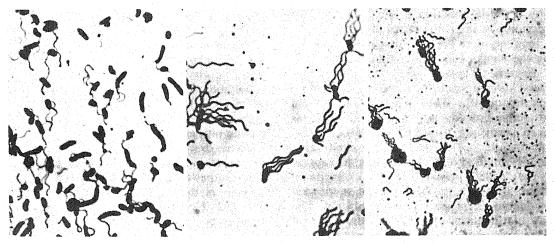

Figure 9. Flagella of bacteria in stained smears examined with the optical microscope. Left, single polar flagellum of a water vibrio; center, peritrichous flagella of Sal. typhimurium; right, peritrichous flagella of Rhizobium leguminosarum. × 2000. (Kral.)

that the flagellar protein, for which the name flagellin has been suggested, is similar to keratin, myosin, epidermin, and fibrinogen. Two patterns are observed, the one suggesting polypeptide chains folded in the α -configuration, and the other the cross- β -configuration regarded as characteristic of actively contracted muscle. This has been taken to imply that the motion of flagella attached to the living cell is a result of rhythmic interchanges between the two configurations. 6

The motion of flagella is apparently random; fibrous internal conducting structures found in ciliates seem to have no counterpart in the motile bacteria, and such a "primitive nervous system" is lacking. The seemingly coordinated motion of flagella is a hydrodynamic phenomenon, occurring when the random flagellar motions of a multiflagellar bacterium coincide by chance to initiate movement of the cell. 17, 47, 77

The energy expenditure required for motility has been calculated⁷³ to be about 14 electron volts per second, or, assuming a 25 per cent efficiency, a total output of 56 electron volts per second. Further, the analogy between muscle fibers and the observed contraction of isolated flagella in the presence of ATP has been taken to suggest that the source of energy is that liberated in the metabolism of energy-rich phosphate bonds, with about 150 bonds reacting per second. Since each flagellum flicks 10 to 20 times per second, and assuming 10 to 20 flagella on a peritrichous bacterium, it is possible

that each flick is the consequence of a discrete metabolic event, such as the breakdown of an energy-rich phosphate bond.

Fimbriae. In a study of bacterial flagellation. Houwink and van Iterson⁴⁵ described minute filamentous appendages on some kinds of flagellated bacteria which have subsequently been referred to as pili, bristles, filaments, and fimbriae; the last appears to have gained some general acceptance. Studies by others¹⁵ have shown that fimbriae are less rigid than flagella, and considerably smaller, 10×300 to 1000 m μ , 100 to 250 per bacterial cell. In the case of dysentery bacilli they appear to facilitate adherence of the bacteria to the intestinal mucosa and, in the Flexner dysentery bacilli, contain an antigen common to the several serotypes (Chap. Twenty-two). Not all flagellated bacteria have fimbriae, and as yet their significance is uncertain.

Capsules. 110, 111 Many bacteria, probably all if grown under appropriate environmental conditions, are surrounded by a layer of gelatinous, poorly defined, and poorly staining material that has been variously termed the capsule, slime layer, or envelope. While there is a tendency to apply one term to one kind of bacterium and another to another kind, viz., the capsule of the pneumococcus, the slime layer of Leuconostoc, and the envelope of the plague bacillus, the terms are, for all practical purposes, interchangeable. Among the pathogenic bacteria, the presence of a capsule is associated with virulence, not because of

any essential function of the capsule in the economy of the cell, but because it interferes effectively with the ingestion of the bacteria by the phagocytic cells of the body.

Bacterial capsules are not seen in the usual stained smear because of their failure to retain the dye. They may be faintly stained by some procedures, ²⁸ and alcian blue has been reported ⁶³ to stain the capsular polysaccharide, but in general the most satisfactory method of demonstrating the capsule is the "relief" preparation, wet or fixed and dried, in which the bacteria are suspended in diluted India ink (colloidal carbon). The capsule displaces the ink, and the bacterial cells appear to lie in lacunae, representing the capsules, in the dark background.

The relative size of the capsule varies widely. In heavily encapsulated forms, such as pneumococcus and Friedländer's bacillus, the thickness of the capsule is frequently greater than the diameter or breadth of the cell and is often continuous over adjacent cells such as diplococci or streptococci. In other bacteria it may be much smaller, no more than a thin layer about the cell, but still demonstrable, and in still others the capsule is too small to be directly demonstrable even though capsular material may be shown to be present by chemical and immunological methods. The size of the capsule is somewhat dependent upon the method used for its demonstration, i.e., drying and fixing tends to shrink it; it is generally agreed that wet relief preparations give the most accurate results.

The nature of capsular substance. The nature of the material making up the bacterial capsule has been of considerable interest, in large part because in a number of instances the formation of antibody to the capsular substance of pathogens is the most significant element of the effective humoral immune response.

The capsular substance of most, but not all, bacteria is polysaccharide which may or may not contain nitrogen, and which may give sugar acids, amino sugars, and organic acids as well as monosaccharides on hydrolysis. For example, the capsular material of type 2 pneumococcus is a polymer of glucose. That of type 3 pneumococcus is more complex and consists of glucose and glucuronic acid linked at the 1 and 4 positions respectively to give $4-\beta$ -glucuronosidoglucose, or cellobiuronic acid, and these

aldobionic acid units are polymerized by union at positions 1 and 3 to give chains having molecular weights as high as 140,000. The capsular substance of type 1 pneumococcus contains nitrogen and appears to be a polymer of trisaccharide made up of two uronic acid (in part galacturonic acid) moieties together with a third component containing nitrogen and acetyl groups.

Some bacterial capsules may contain mucoprotein admixed with polysaccharide, but whether this is to be regarded as a constituent of the capsule or a contaminant is not clear. However this may be, the marked superiority of the encapsulated bacterial cell to purified polysaccharide in stimulating antibody formation suggests that at least some of the polysaccharide may be linked to protein in the living cell.

Other bacterial capsular materials, especially in the genus Bacillus, are polypeptide in nature. That of the anthrax bacillus is a D-glutamyl polypeptide, while those of nonpathogenic species contain both D-glutamic acid and the naturally occurring isomer also, to as much as 20 per cent. In these forms the polypeptide does not appear to be mixed with polysaccharide. The capsular material of the tubercle bacillus seems to be a special case in that it contains relatively large amounts of nucleic acids admixed with polysaccharide.

The capsule is a loose structure that does not interfere with permeability. Since the enzymatic depolymerization of the capsular substances, such as the pneumococcal polysaccharide and the hyaluronic acid capsule of some hemolytic streptococci, appears neither to damage the cell wall nor affect viability, the capsule is regarded as a structure distinct from the cell wall in many bacteria. In some cases, however, notably the glutamyl polypeptide of Bacillus, there is evidence that depolymerization results in some damage to the cell wall, and it may be inferred that the capsular substance is also a part of the cell wall structure.

In a more restricted sense the capsule hardly attains the dignity of a cell structure in that the capsular substance is an end product of metabolism that is continuously secreted, or excreted, into the surrounding environment. Thus its size is a function of the rate of its formation and secretion and of its continuous solution at the periphery. While in most cases it is presumably formed

intracellularly, in some instances it may be produced outside the cell, perhaps at the cell surface. For example, cell-free culture fluid of *Leuconostoc mesenteroides*, a bacterium associated with slime formation in the sugar refining processes, polymerizes sucrose to the dextran capsular substance of this bacterium.

The specific capsular reaction. As indicated above, the capsular substance is antigenic, functioning largely as a partial antigen or haptene. It reacts specifically with homologous antibody to produce a microprecipitation in the capsule, altering its refractive index so that it appears better defined in wet unstained preparations.

This phenomenon was described in 1896 by Rogers, working with the fungus Oidium, and by Neufeld in 1902 for the pneumococcus, as a swelling of the capsule, the Ouellung reaction. This reaction allows rapid serological identification and has been applied to several groups of streptococci, the meningococcus, the influenza bacillus, Friedländer's bacillus, some of the coliforms. and to Pasteurella and Bacillus species, as well as to the pneumococcus. There appears to be some question as to whether actual swelling occurs. Careful measurement has shown that in most cases an increase in size cannot be demonstrated, but in some instances, such as pneumococcus, it may occur. Since one pneumococcus combines with 4×10^6 antibody molecules which, when packed, have a volume of about $0.8 \mu^3$, but increases in volume from 2.8 to 9.8 μ^3 , swelling in addition to the volume occupied by the immune globulin has occurred. 48 Such swelling may be a consequence of several factors such as a secondary hydration and an increased viscosity that retards diffusion.

The reaction of capsular substance with immune serum globulin also occurs with other proteins under appropriate conditions. It appears to consist of a salt-like combination between the capsular substance and proteins such as casein, various albumins and globulins, and hemoglobin at a low pH on the acid side of the isoelectric point of the protein. This capsular reaction differs from that with homologous antibody in that it is nonspecific and pH dependent.

STAINING REACTIONS

As implied before, the intact bacterial

cell stains readily with basic dyes such as crystal violet, methylene blue, and basic fuchsin but relatively poorly with acidic dyes such as eosin. While irregular staining with differentiation of more deeply staining areas or granules is observed in old cells and is characteristic of a few kinds of bacteria, most bacteria stain uniformly without the differentiation of internal structure that is readily demonstrable in, for example, mammalian tissue cells.

This marked affinity for basic dyes is indicative of an acidic protoplasm containing unusually large amounts of nucleoprotein more or less uniformly distributed. This inference is substantiated by a high content of purine and pyrimidine nitrogen in the bacterial cell, and ribonucleic and deoxyribonucleic acids make up from 5 to as much as 30 per cent of the dry weight of the cell substance.

The staining reactions of the intact bacterial cell are remarkably uniform with two important exceptions. These are the reaction to the Gram staining procedure and the high resistance to both penetration of dye and decolorization characterizing the so-called acid-fast bacilli.

The Gram-stain. This differential staining procedure was devised by the histologist Christian Gram as a method of staining bacteria in tissues, and described in 1884. It is an arbitrary procedure consisting of four steps, viz., (1) primary staining with crystal violet, usually containing a mordant such as ammonium oxalate; (2) the application of dilute (1:15) Lugol's iodine solution; (3) decolorization, most commonly with 95 per cent ethanol; and (4) counterstaining with a dye of contrasting color, usually safranin. When bacteria are stained by this method. they are separated into two groups. The gram-positive bacteria are those which retain the primary stain and are deep violet in color, and the gram-negative bacteria are those which are decolorized and are lightly stained by the counterstain, pink in the case of safranin.

The gram-positive reaction is relatively rare. It occurs only among the bacteria, yeasts, and filamentous fungi. A very few biological structures are gram-positive; they are those which are thought to be autore-producing, and they include chromosomes of certain species, mitochondria, centrosomes, and centromeres.

The reaction of bacteria to the Gram stain is correlated with a number of other characteristics, and representative differences are shown in the accompanying table. Such differences are only relative and are not completely consistent. The gonococcus, for instance, though gram-negative, behaves in many respects, such as susceptibility to the antibacterial activity of penicillin, as if it were gram-positive.

There are also significant differences in the permeability of bacterial cells to amino acids, glutamic acid and lysine in particular, that are associated with the Gram reaction. Gram-positive bacteria are distinguished by their ability to concentrate such amino acids from the environment, while their synthesis occurs intracellularly in gramnegative bacteria,34 an observation that may be linked with the relative complexity of the nutritive requirements of the gram-positive forms. Differences between bacteria correlated with the Gram reaction reach an impressive total and suggest that reaction to the Gram stain is a reflection of fundamental differences between the two kinds of bacteria. Consequently, the mechanism of the Gram reaction has been of considerable interest.

Three kinds of theories have been proposed to account for the Gram stain reaction. A differential permeability to the alcohol-soluble dye-iodine complex was proposed by Benians; a difference in isoelectric point of the cell contents between the gram-positive and gram-negative bacteria was urged by Stearn and Stearn on the assumption that a lower iso-electric point in the gram-positive bacteria would

result in a more stable complex with the basic dye of the primary stain; and, finally, it has been postulated, largely by Churchman, that the site of the Gram reaction is in the outer layers, or cortex, of the cell, the internal material being gram-negative in both kinds of bacteria.

Each of these is supported to some degree by available evidence, but none to the exclusion of the others. In general, the Gram reaction appears to be a property of the entire cell and to be associated with some cell components. The most precise evidence in this connection is the presence of a magnesium ribonucleate - protein complex in the gram-positive bacteria which is not present in gram-negative bacteria. This material can be removed from gram-positive cells by solution in bile to leave a gram-negative "cytoskeleton" and redeposited to make the cells gram-positive again. Gram-positive bacteria may also be made gram-negative by treatment with ribonuclease, and it has been possible to replace the bacterial ribonucleate with yeast ribonucleate. It has not, however, been possible to make naturally occurring gram-negative bacteria gram-positive by treating with the ribonucleate complex obtained from gram-positive bacteria.

There is also evidence associating the Gram reaction with other cell components, lipid and polysaccharide. Nevertheless, the mechanisms operative in the Gram reaction are still poorly understood, and the basic differences between the two kinds of bacteria, associated with or reflected in other properties, are not resolved.

The acid-fast stain. It was early observed that some kinds of bacteria are difficult to

Differences Between Gram-Positive and Gram-Negative Bacteria

GRAM-POSITIVE BACTERIA		GRAM-NEGATIVE BACTERIA
More susceptible	Antibacterial activity of basic dyes, anionic and cationic detergents, phenol, sulfonamides, penicillin	More resistant
More resistant	Antibacterial activity of azides, tellurites, oxidizing agents, streptomycin	More susceptible
More resistant	Digestion by proteolytic enzymes, lytic action of alkali	More susceptible
More complex	Nutritive requirements	Simpler
11-22% lipid	Cell wall composition	1-4% lipid
All amino acids present		Lacking some amino acids

stain and equally resistant to decolorization with highly effective agents such as acid-alcohol, and because of the latter were termed acid-fast. In this respect they resemble superficially the bacterial spore. These bacteria form a homogeneous group, the acid-fast bacteria, making up the genus Mycobacterium, which includes the tubercle and leprosy bacilli together with pathogens of cold-blooded animals and saprophytic forms.

These bacteria are characterized by a high, as much as 40 per cent of the dry weight, lipid content. These bacterial lipids have been studied in some detail, especially those of the tubercle bacillus, and have been found to consist largely of phospholipid and wax. The unsaponifiable portion of the wax fraction includes higher alcohols, one of which, a saturated hydroxymethoxy acid named mycolic acid, is associated with the property of acid-fastness. Mycolic acid may be regarded as the substrate in this staining reaction, and the property of acid-fastness, confined to these bacteria and some actinomycetes, appears to be a consequence of a relatively greater solubility of the phenoldye in the cellular lipids than in the decolorizing agent.

Neither the Gram reaction nor the acidfast property of some bacteria gives information about the morphological structure of the bacterial cell, but they are concerned with its chemical structure. In the first instance chemical structure is associated with other properties of the cell as noted above, and in the second with immunological phenomena and pathogenesis in the case of pathogenic forms.

THE CELL WALL AND PLASMA MEMBRANE

The occurrence of bacteria in shapes other than spherical is evidence of a rigidity of structure sufficient to withstand the forces of surface tension. While the gel-like state of the protoplasm may contribute in part to such rigidity, the cell structure largely responsible is the cell wall. It was not possible to demonstrate unequivocally the presence of a cell wall in bacteria until relatively recently when newer techniques, especially electron microscopy, became available. It is now apparent that the outer structure of the bacterial cell is dual in nature and consists of the cell wall proper and the plasma membrane which lines the inner surface of the cell wall.

The cell wall. 80, 89, 103 The cell wall is not apparent in the usual stained smear, but when the cytoplasm has been shrunk away by boiling the cells in dilute alkali it is demonstrable in crystal violet-stained smears. It may also be stained by Dyar's method in which Congo red is used with cetyl pyridinium chloride as a cationic mordant.

When the bacterial cell is shattered by physical means such as sonic or ultrasonic vibrations, the cell wall fragments do not tend to round up but show jagged lines of fracture. In electron micrographs of cell wall fragments the structure appears to be a collapsed sac, but this is an artifact due to

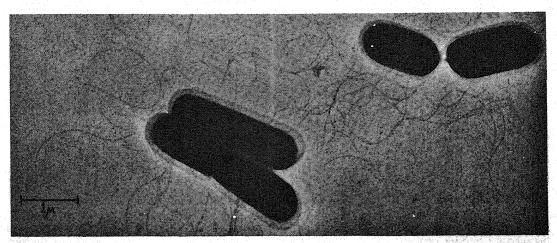

Figure 10. Electron micrograph of Clostridium tetani from 24-hour culture showing the clear cell walls and peritrichous flagella. (Mudd and Anderson.)

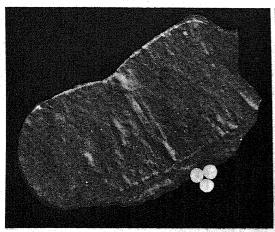

the effects of surface tension forces operative during the process of drying. When the cell walls are dried from the frozen state this is avoided, and rod-shaped forms, for example, are cylindrical in shape. Data such as these strongly support the concept of the cell wall as a structure having rigidity as well as ductility and elasticity apparent in the intact cell.

Cell wall preparations. Bacterial cell walls may be prepared free of intracellular material in a number of ways. Mechanical disintegration of the cells has the advantage that it avoids chemical alteration of the cell wall substance, provided that autolysis by the freed microbial enzymes does not occur. This is accomplished by grinding, shaking with small glass beads, or by sonic or ultrasonic disruption.

Bacteria vary in their resistance to such mechanical disruption. In the Mickle tissue disintegrator,68 in which the bacterial suspension is mixed with small glass beads such as glow beads and the containers shaken by a vibrating tuning fork, the time required for disruption of 95 per cent or more of the cells varies from 5 minutes for fragile bacteria such as the cholera vibrio to as much as an hour for staphylococcus. Similar results are obtained by subjecting the bacterial suspension to sonic vibration at 9 to 10 kc. or ultrasonic vibration at 20 to 40 kc. Some bacteria are highly resistant to the latter kind of treatment, especially staphylococci and streptococci, and in general gram-positive bacteria are more difficult to break up by mechanical means than are gram-negative bacteria. The cell walls are separated from the liberated cell contents by centrifugation and, after repeated washing with distilled water or molar sodium chloride solution, are free of electron-dense particles, nucleic acids, etc. Cell walls so prepared retain substantially all their original properties, for example, will adsorb bacteriophage (Chap. Four), are stable and resistant to digestion with trypsin, ribonuclease, and deoxyribonuclease.

Properties of the cell wall. Studies on such preparations have shed considerable light on the nature of the cell wall. It is thinner in gram-negative bacteria than in grampositive bacteria, ranging in general from 10 to 25 m μ in thickness, makes up about 20 per cent of the dry weight of the cell, has an effective pore diameter of 1 to 2 m μ , and is permeable to molecules are large as nucleotides.

While the cell walls of most kinds of bacteria appear to be homogeneous in electron micrographs, those of others, notably Spirillum, are made up of spherical macromolecules, ranging from 50 to 150 m μ in diameter but constant within species, arranged in regular, hexagonal or rectangular, patterns. 44, 53, 90 Assuming a regular packing of such macromolecules, the interstices correspond approximately to the effective pore diameter determined by permeability studies.

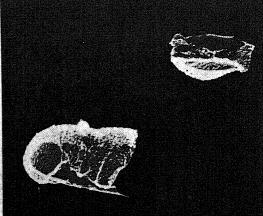

Figure 11. Cell walls of *Bacillus megaterium*. Left, an air-dried preparation which superficially exaggerates the size of the cell; the thickened band represents cell wall synthesized during the early stages of cell division, and the spherical particles are latex. × 11,500. Right, freeze-dried preparation showing the three dimensional structure of the cell wall, corresponding more closely to the size of the intact cell. × 12,250. (Salton and Williams.)

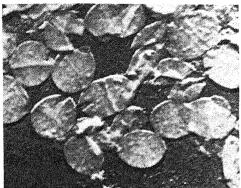

Figure 12. Cell wall preparations. Left, unwashed cell walls of Streptococcus fecalis prepared in the Mickle apparatus, showing the splitting of the cell wall which allows the contents to escape, the small electron-dense bodies adhering to the cell wall, and the thickened bands occurring in the early stages of cell division. \times 12,000. Right, freeze-dried preparation of the cell wall of Rhodospirillum rubrum showing the spherical bodies of the cell wall of this microorganism. \times 42,000. (Salton and Williams; Salton and Horne.)

The cell wall substance consists of peptide, polysaccharide, and lipid, highly individualistic in kind and amount in different bacterial species. 119 The hydrolysis products of the peptide include glucosamine, D- and L-alanine, D-glutamic acid and either Llysine, DD- or LL- or $meso-\alpha-\epsilon$ -diaminopimelic acid, 2,4-diaminobutyric acid, or either D- or L-ornithine. These substances occur in the cell wall as covalent-linked polymers, and have been termed mucopeptides, glycopeptides, glyco-amino peptides, or mureins, differing in composition from one kind of bacteria to another. The mucopeptide structure appears to be the mechanical support maintaining the shape of the bacterial cell.

The polysaccharides hydrolyze to sugars such as rhamnose, galactose, glucose, mannose, and arabinose. That of the diphtheria bacillus has been found,⁴¹ for example, to be an oligosaccharide made up of two molecules of D-galactose, one of D-mannose, and three of D-arabinose, and to have a molecular weight of about 1000. Hexosamine is found regularly and probably exists in the cell wall as N-acetylhexosamine though not as a chitin-type polymer.

Relatively large amounts of phosphorus are present as ribitolphosphate and glycerophosphate polymers. These complexes contain other substances, e.g., α -glucosyl and O-alanyl residues, and are called teichoic acids.

While, as indicated above, bacterial cell walls are not digested by trypsin, those of a number of kinds of bacteria, including cer-

tain of the micrococci and Bacillus, are broken down by lysozyme, the bacteriolytic agent found in lacrimal and other secretions, egg white, etc. The substrate of lysozyme in the bacterial cell wall is a hexosamine-containing mucocomplex or mucopolysaccharide, but the enzymatic breakdown is incomplete in that the major products of degradation have molecular weights of 10,000 to 20,000. The dissolution of the cell wall by lysozyme, then, is not a matter of complete digestion, but rather a degradation of a component of the cell wall that may bind the major peptide and polysaccharide components, with breakdown of the cell wall as a structure. Lysozyme hydrolyzes the β 1-4 linkages between N-acetylmuramic acid and N-acetylglucosamine, and the cell walls of lysozyme-sensitive bacteria contain appropriately linked repeating units of these substances.

It has been observed also that the cell wall is depolymerized as a supporting structure in immune lysis (Chap. Fourteen); this has been attributed to the activity of lysozyme present in the serum reagents. In at least one instance,³¹ however, cell wall is depolymerized in the presence of the antibodycomplement complex in the absence of demonstrable lysozyme, and the osmotic fragility of the resulting protoplasts (see below) produces death of the cells in the immune bactericidal reaction.

The cell walls of streptococci are resistant to the action of lysozyme but are broken down by enzymes produced by *Streptomyces albus* and other actinomycetes.^{62, 88}

268440

5760

Bacterial cell walls attacked by lysozyme are not affected by these enzymes, indicating that a different substrate is involved. The products of degradation are, however, similar to those produced by lysozyme.

The plasma membrane. The plasma, or cytoplasmic, membrane of the bacterial cell lies on the inner surface of the cell wall, separating it from the cell plasma. On mechanical disruption of the cell, fragments of the membrane may be seen attached to the broken cell wall, and it may be stained in the cell by appropriate techniques. The membrane, on separation from the cell wall and debris of fragmented cells, breaks up into the so-called small particle fraction that may be removed by differential centrifugation.

The plasma membrane substance appears to be a complex lipoprotein, containing 40 per cent protein and 20 to 25 per cent lipid, and makes up about 10 per cent of the dry weight of the cell.⁷¹ These and related data may be taken to indicate that it conforms to the classic concept of lipoprotein membranes and is, in the intact cell, a closely packed lipoprotein sheet, two to four molecules thick, and about 15 m μ thick in the hydrated form.

The bacterial membranes differ from mammalian membranes in a number of ways: viz., sterols appear to be absent except in the case of Mycoplasma, little or no phospholipid of the glyceryl phorphoryl choline type is found though glyceryl phorphoryl ethanolamine lipids are present, there are relatively large amounts of unesterified polyglyceryl and glyceryl phosphates, and oddnumbered branched chain fatty acids are present in large proportion. The significance of such differences in chemical composition is as yet uncertain.

This membrane has little mechanical strength and does not contribute significantly to maintenance of cell shape as shown by the rounding up of the bacillary form after removal of the cell wall by enzymatic digestion (see below). It is forced against the cell wall by a hydrostatic pressure, as much as 20 atmospheres, corresponding to the osmotic pressure differential across it. While it is a structure distinct from the cell wall in that the two differ in chemical composition and enzyme content, the two are joined by more than lateral cohesion. Thus, the plasma membrane is broken up in the

absence of the cell wall by chilling, but much less readily in the intact cell, and it may be inferred that some sort of bonding occurs between the two structures such that rearrangement of parts of the membrane to give freely permeable areas is inhibited.

Osmotic regulation.⁷² While the cell wall and plasma membrane are distinct, artificially separable structures, in the bacterial cell they make up an integrated unit whose function is, in part, that of an osmotic barrier and regulatory mechanism separating the cell plasma from the suspending medium and implementing, for the bacteria, Claude Bernard's concept of the relatively isolated environment required by free-living organisms.

The contribution of the cell wall to this joint function is largely that of a supporting structure, but it also contributes to the permeability of the intact cell in that it acts as a barrier to substances having molecular weights of 10,000 or more. While this is not essential to the physiological economy of the cell (see below), it does provide some protection against large molecular weight substances such as antibodies and lytic enzymes. The plasma membrane functions as the significant osmotic barrier to lower molecular weight substances and exhibits the usual properties of living semipermeable membranes such as selective permeability and the transport of substances across the barrier against concentration gradients.

The bacterial cell is apparently freely permeable to the sodium ion, with rapid equilibration between internal and external concentrations. The potassium ion, however, may accumulate intracellularly against a concentration gradient; the process is associated with exergonic metabolism and is inhibited in the presence of 2-4-dinitrophenol, sodium azide, and similar respiratory poisons.

Relatively precise studies of bacterial permeability to amino acids, lysine and glutamic acid particularly, have been carried out with a few species of bacteria, and there appear to be significant differences between the gram-negative and gram-positive forms. It is generally said that the gramnegative bacteria are freely permeable to amino acids while the gram-positive bacteria are not. This appears not to be strictly true for, on the one hand, the occurrence of internal amino acid pools is demonstrable

in at least some gram-negative bacteria, and, on the other, the gram-positive bacteria studied seem to be at least partially permeable to some amino acids although the accumulation of others involves active transport and a source of energy. Thus, while lysine appears to diffuse readily in both directions across the osmotic barrier, and is independent of exergonic metabolic activity, at the same time intracellular lysine cannot be washed out of bacterial cells suspended in distilled water unless glucose is present.

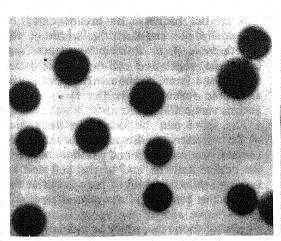

Permeases.25 There is evidence that the active transport of nutrient substances across the osmotic barrier is a function, at least in part, of enzymatic activities to which the name permeases has been given. Such a permease is essential to the utilization of lactose by some strains of coliform bacilli. e.g., the appropriate enzyme, β -galactosidase, may be present within the cell, but unless the transport mechanism is present, the sugar is not utilized. The permease activity is genetically controlled, and cells which lack it, but contain β -galactosidase, are designated cryptic mutants (Chap. Seven), i.e., metabolically inert in the presence of the substrate. A considerable number of such permease activities have been described.

Bacterial permeability is of particular interest in connection with the nature of the effect of antibacterial substances characterized by bacteriostatic or growth-inhibiting activity such as the chemotherapeutic drugs, the basis of reversal of antibacterial

activity, and the nature of drug resistance as related, for example, to altered permeability to amino acids such as glutamic acid.³³ The evidence, though meager in contrast with that available for classic subjects of permeability studies such as Arbacia eggs and erythrocytes, suggests that an active transport mechanism or exchange diffusion is involved, with reversible deformation of parts of the plasma membrane to allow passage of the carrier.⁶⁹ This raises the interesting possibility that some kinds of antibacterial activity may result from effects on a carrier mechanism and/or the structure of the osmotic barrier.

Bacterial protoplasts. 13, 65, 115 On enzymatic degradation of the cell wall of the living bacterial cell, as for example by treatment of Bacillus species with lysozyme, the cell first swells, then the protoplasm becomes partially detached from the disintegrating cell wall, and finally, following complete dissolution of the cell wall, the cell content assumes a spherical shape. This spherical form, the cell protoplasm enclosed in the plasma membrane, is the protoplast.

The protoplast is a fragile structure because the plasma membrane has little mechanical strength. When the cell wall is removed by enzymatic dissolution in physiological saline, the protoplasts begin to break up almost as soon as they are formed, first to an empty membrane or "ghost," followed by fragmentation of the membrane. 112 It was found by Weibull that sucrose and polyethylene glycol act as stabilizing agents, and it is now established that if

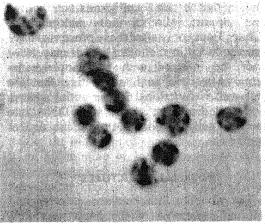

Figure 13. Protoplasts (left) and protoplast ghosts (right) of Bacillus megaterium. Note the spherical shape assumed by the bacillary form on dissolution of the cell wall. Phase contrast photomicrographs. × 3000. (Weibull.¹¹⁴)

the cell wall is removed from cells suspended in mediums such as 0.1 to 0.5 molar sucrose, 7.5 per cent polyethylene glycol, 0.25 to 0.5 molar sodium chloride, or 0.5 molar phosphate at pH 7, the protoplast is relatively stable over a period of several hours if kept under semi-anaerobic conditions and protected from shock. Stabilized protoplasts suspended in 0.2 molar sucrose solution containing magnesium salts at concentrations of 0.01 molar or greater may be lysed by reduction of the sucrose concentration to give stable "ghosts." When the cell wall is damaged so as to affect its structural integrity, but remains present, the bacterial cell also rounds up in spherical form, and is known as a spheroplast.

Physiological studies on stabilized protoplasts have shown that the competence of the intact cell persists almost, but not quite, entirely in the protoplast and indicates the function of the cell wall by implication. Protoplasts show a high endogenous respiratory rate $(QO_2 = 66)$ and can oxidize glucose. They are able to incorporate C14 in protein and nucleic acid at rates only slightly less than those of actively growing intact cells. The path of incorporation of acetate carbon is consistent with the operation of the tricarboxylic acid cycle in providing intermediates for amino acid synthesis⁶⁴ indicating that actual synthesis rather than exchange is involved, and the synthetic abilities of the protoplast are further substantiated by the synthesis of the adaptive enzyme β -galactosidase. There is some evidence also that the protoplast is capable of growth and division.

The protoplast differs from the intact cell in that it can form spores (see below) and support bacterial virus multiplication (Chap. Four) only after these processes have been induced in the intact cell. It may, however, be infected with bacteriophage infectious nucleic acid, suggesting that the cell wall is functional in the initial adsorption and discharge of the viral DNA into the host cell, but does not affect subsequent synthesis.

INTERNAL STRUCTURES 57, 76

The dividing line between external and internal structures of the bacterial cell is not a sharp one and is perhaps justified for the most part on little more than a utilitarian

basis. Thus, in a sense the protoplast is a subcellular element, yet flagella remain attached to it since the basal granules at or near the inner surface of the cell wall in which they originate are apparently not an integral part of the cell wall structure because they remain after enzymatic dissolution of the cell wall. Similarly, the bacterial spore is formed within the cell, but it represents a stage in the life history of the bacterium rather than a subcellular structure in the ordinarily accepted sense.

spore. 30, 36, 104, 108 The bacterial formation is uncommon among the bacteria and is confined largely, if not entirely, to the bacilli. The aerobic spore-forming bacilli make up the genus Bacillus, and the obligate anaerobic or micro-aerophilic bacilli that form spores are members of the genus Clostridium. Both are widely distributed in nature. Members of the former group are saprophytic forms found in soil, dust, and water and, with the exception of the anthrax bacillus, are not pathogenic for man under ordinary circumstances. The anaerobic group is similarly distributed and includes both saprophytic nonpathogenic forms together with microorganisms which are pathogenic by virtue of toxin formation, such as the tetanus and gaseous gangrene bacilli and the botulinus bacilli, although they are not obligate parasites.

The bacterial spore is a refractile oval body formed within the bacterial cell and found both intracellularly and extracellularly in the usual stained smear; the vegetative cell substance has disintegrated about those lying free. Within the cell, the long dimension of the spore is parallel with the long axis of the bacillus. Its breadth may be essentially the same as the width of the vegetative cell, or it may be greater and bulge the vegetative cell wall. The latter appearance is most commonly found in the anaerobic forms and is the basis of the generic name Clostridium.

The spore may be located in the center of the vegetative cell, where it is said to be central, or it may be found part way between the center and the end of the cell and be subterminal, and finally it may occur at the end of the cell and is designated terminal. The relative size of the spore is constant, and its location reasonably so within species. Its size and location may result in a characteristic morphology, e.g., the large ter-

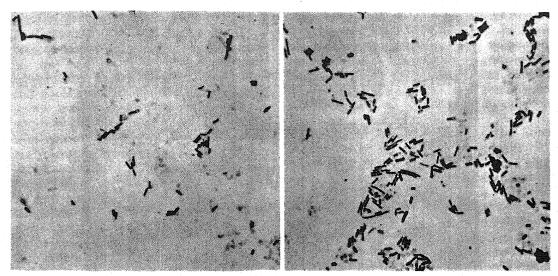

Figure 14. Spore formation by pacteria. Left, Clostridium botulinum type B, showing the typical clostrispores separated from disintegrated vegetative cells. Right, Clostridium sporogenes, showing a subterminal clostridial spore. These preparations are all stained with a single stain in the usual way; the vegetative cells take up the dye, but the spores remain unstained. Fuchsin; × 1050.

minal spore of the tetanus bacillus gives the spore-containing vegetative cell a drumstick appearance.

In the usual stained smear the spore appears as an unstained refractile body within the stained vegetative cell, and some stain may adhere superficially to free spores to accentuate their outlines. In electron micrographs of ultrathin sections, it is apparent that the spore consists of a dense central core, a fibrillar cortex, and an outer coat. The spore may be stained by using heat and/or mordants. Once stained, it is equally difficult to decolorize with the usual reagents such as alcohol, acid-alcohol, and alcoholacetone. Consequently, differential staining of the spore is a simple matter; for example, the smear may be stained with hot carbolfuchsin, decolorized with alcohol, and counterstained with a dye of contrasting color, such as methylene blue to give a red spore in a blue vegetative cell.

The spore has a low, but measurable, endogenous metabolism, about $0.3~\mu l.~O_2$ consumed per hour per mg. dry weight. It is characterized by an increased calcium content over that of the vegetative cell, and the presence of dipicolinic acid (pyridine 2,6-dicarboxylic acid) contained in the outer coat.

The factors involved in spore formation are poorly understood, but in general spores are formed most readily under optimal con-

strickersen de di velle di

ditions for growth, and spore formation begins toward the end of, or just following, the period of exponential growth. There is no reason to believe, as is sometimes supposed, that spore formation occurs in response to adverse environmental conditions.

The effects of environmental conditions on spore formation vary from one kind of bacteria to another. For example, the aerobic anthrax bacillus forms spores only under aerobic conditions, and spores are not found in impression smears of organs such as spleen from animals dead of anthrax since the tissues are not sufficiently aerobic to permit sporulation. Similarly, the anaerobic sporulating bacilli do not form spores under aerobic conditions that do not allow growth. The temperature of incubation may be a factor also, and it is common knowledge that aerobic sporulating bacilli do not form spores when grown at maximal temperatures tolerated for growth, and, in fact, permanently asporogenous variants may be produced by continued cultivation at high temperatures.

Cytological observations have shown that at the initiation of spore formation there is an assembling or local concentration of material staining deeply with basic dyes, presumably nucleoprotein, which constitutes the spore primordium or forespore. This may occur with the formation of a granule which enlarges to form the spore in some bacteria, in others there seems to

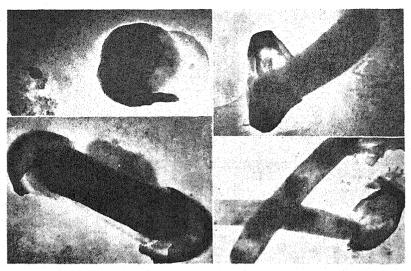

Figure 15. Electron micrographs illustrating the process of germination of spores of *Bacillus mycoides*. In the *upper left* the vegetative cell is just beginning to emerge from the spore case. In the *upper right* the vegetative cell is growing out of the side of the spore case and has broken the case in two parts in the *lower left*. In the *lower right* germination is complete. The darker areas in the vegetative cells are regarded by some as nucleus-like in nature. (Courtesy of Dr. G. Knaysi and the Journal of Bacteriology.)

be an aggregation of deeply staining granules, and in still others only a local concentration unrelated to granules. In any case, when formation is complete the spore assumes the characteristic refractile appearance, and the surrounding vegetative cell sloughs off. Only one spore is formed by a single vegetative cell, and spore formation cannot be regarded as a method of multiplication, and, further, there is no evidence of sexual phenomena or conjugation in the formation of bacterial spores such as occurs among the fungi.

It has been found²⁷ that the spore contains antigens that are not present in the vegetative cell, and this indicates that the process of sporulation is more than an assembling and concentration of vegetative cell substance. The spore antigens are specific in that spores from immunologically different vegetative cell species are distinct and do not share common spore antigens. The spore contains a full complement of the enzymes present in the vegetative cell, though in reduced amount, and is not dormant in that the low endogenous respiration of moist spores is measurable in the usual respirometers.

The composition of the spore does not account satisfactorily for its unusual resistance to injury although the presence of dipicolinic acid is considered by some to be associated with heat resistance. It is not only relatively impermeable to dyes, as

noted above, but also is much more resistant to the injurious effects of heat, drying, many bactericidal chemical compounds, etc., than is the vegetative cell.

Sterilization procedures (Chap. Six) are necessarily directed toward the destruction of the ubiquitous microbial spore. Some bacterial spores, such as those of organisms causing flat sours in canned foods, may be extremely resistant to heat and require heating in steam under pressure at 120° C. for as long as three hours to insure destruction. Most are not this resistant and are killed by moist heat at 115° to 120° C. for 15 to 20 minutes. Still others are destroyed by boiling for a short time, but few if any are killed by treatment at 58° to 60° C. for 30 minutes, which suffices to destroy most bacterial vegetative cells. They are also extremely resistant to drying; the classic example is that of the viability of anthrax spores dried on silk threads in Koch's laboratory after 60 years.

The ratio of the concentration of bactericidal compounds lethal to the vegetative cell to that lethal for the spore is on the order of 10³ to 10⁴ for many disinfectants such as hypochlorites and phenols. Interesting and significant exceptions are the alkylating agents such as ethylene oxide or formaldehyde, for which the ratio ranges from 0.5 to 15.

When the spore is placed in an environment favorable to the growth of vegetative cells it germinates. The factors affecting germination are not well known. It may be delayed and irregular, and in some instances this has been found to be associated with the presence of fatty acids, such as oleic and linoleic acids, in the culture medium. Spores may be germinated mechanically by abrasion of the spore coat with glass heads. with consequent loss of dipicolinic acid.86 but release of dipicolinic acid with surface active agents does not allow further development.87 Or germination may be accelerated by heat shock, a short exposure to a high temperature, say 80° C., prior to culture. Once germination is initiated, it occurs at an exponential rate. Nucleic acid metabolism differs from that of the vegetative cell. at least in the case of Bacillus subtilis, with a preliminary synthesis of RNA during the first two hours, followed by initiation of DNA synthesis. Dipicolinic acid is excreted during germination and is not found in germinated spores or vegetative cells.

The first microscopic evidence of germination is a change in the refractile appearance of the spore, and it becomes more permeable to dyes and takes up dye like the vegetative cell. The sequence of events thereafter is variable. The spore wall may become thin and stretch and assume the shape of the vegetative cell. In other instances the vegetative cell appears to grow within the spore wall which is split and cast off as a hull. The anthrax bacillus grows out of one side of the spore wall, while the

Figure 16. Recently germinated vegetative cells of Bacillus mesentericus, showing discarded spore cases. Note the cell boundaries in the long filaments made up of cells attached end to end. The deeply staining areas are chromatinic bodies. Osmium tetraoxide-hydrochloric acid fixation, Giemsa; × 4000. (Robinow.)

closely related *Bacillus subtilis* grows out of opposite sides simultaneously. In *Bacillus megaterium* the spore case splits along the equatorial ridge or groove, allowing the vegetative cell to emerge. Other bacteria have intermediate methods of germination, and irregularities may occur in the development of spores into vegetative cells in the same bacterial species. It is to be noted that, as the vegetative cell produces only one spore, on germination the spore gives rise to only a single vegetative cell, and the process of germination is not of multiplication.

The biological function of the bacterial spore is not known. It is clearly a normal stage in the life history of the spore-forming bacteria, and may be regarded as a resting stage, possibly analogous to hibernation or estivation in higher forms. Its high resistance to injury serves to carry the bacterial species through unfavorable circumstances, and the spore might be supposed to have survival value.

The bacterial nucleus. 32 The bacteria contain very large amounts of nucleic acids by analysis, more than most other kinds of cells, and the usual uniform staining of the bacterial cell by basic dves is indicative of their general distribution within the cell. Like other organisms, but with the exception of the viruses (see below), bacteria contain both deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). The DNA is contained largely in masses or bodies within the cell, while the RNA occurs in the surrounding cytoplasm. This localization of DNA is masked in the conventional stained preparation since the RNA is stained also, but is demonstrable by staining if the RNA is selectively removed by mild acid hydrolysis or treatment with ribonuclease, or is deficient as in starved cells growing on a nutritionally minimal medium. The masses of DNA, or chromatinic bodies, generally stain only weakly with the basic dyes, though they may be stained with mordant and fuchsin, but stain strongly with Giemsa and are Feulgen-positive.*

^{*}The Feulgen reaction is a microchemical test for the presence of DNA. The aldehyde group of acidhydrolyzed DNA react with Schiff's reagent to restore the color to the reduced fuchsin, and aggregates of DNA appear as violet-colored masses. The test is one for free aldehyde groups and is not specific for DNA.

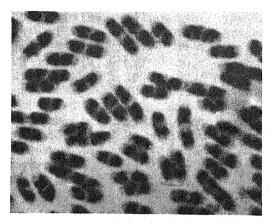

Figure 17. Light microscope photomicrograph of a two and one-half hour culture of colon bacilli, fixed with osmium tetraoxide vapor and alcoholic mercuric chloride, hydrolyzed at 56° to 60° C. with normal hydrochloric acid, and stained with Giemsa. The deeply staining bodies are chromatinic bodies. (Robinow.)

It is obvious from the persisting identity of a given strain of bacteria that a heredity-controlling mechanism must be present, and it has become clear that the chromatinic bodies are nuclei with respect to function. There are one to two per cell, or three to four in actively multiplying bacteria, and they replicate coincident with cell division to occur in the daughter cells. At the same time, they are relatively simple in structure and are not enclosed within a limiting membrane, and reports of the occurrence of mitotic figures seem not to be well founded. There is, therefore, some reservation as to the complete identity of the chromatinic

bodies with nuclei in the conventional sense, and they are commonly termed nucleoids.

The morphology of the bacterial genetic apparatus has been determined in large part from studies on the recombination of inheritable characters during bacterial coniugation38 (Chap. Seven). It has been established that individual genetic determinants are arranged in linear order, and the entire genome is contained in a single DNA duplex which, when fully extended, is 100 to 1400 μ long. This structure has been directly observed in elegant experiments by Cairns¹⁹ and by Kleinschmidt and co-workers. 51 In the first instance tritium-labeled DNA was released by lysis of the bacterial cell with Duponol and allowed to disentangle on the surface of a dialysis membrane, which was in turn overlaid with photographic emulsion. and radioautographs were made. In the second instance protoplasts were lysed in a spreading monomolecular protein film at an air-water interface, shadow-cast, and examined by electron microscopy. No free ends were observed, and this is consistent with the inference from conjugation studies that the E. coli chromosome is circular in contrast to that of T₂ coliphage, which is linear. But transfer during conjugation is linear, and it is evident that the circular chromosome must be broken to allow such transfer. The mechanism by which breakage occurs and polarization for transfer takes place is highly controversial. Evidence has been adduced, largely by Jacob, Monod, and their co-workers, that the point

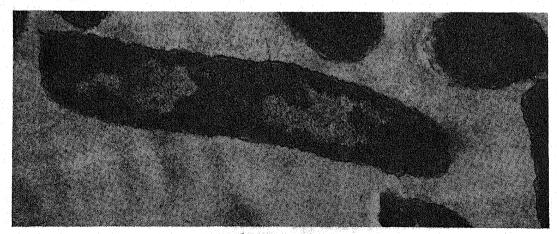

Figure 18. The DNA chromatinic bodies in *Escherichia coli* K-12S during the exponential growth phase. Note the apparent lack of a limiting membrane. Section fixed in osmium tetraoxide. × 40,000. (Kellenberger.)

at which the circular chromosome is opened lies within the sex factor (Chap. Seven) and the chromosome is in contact with the plasma membrane at this point, but this is not unequivocally established.

Since the bacterial chromosome is perhaps a thousand-fold longer than the nucleoid, it follows that it must be folded or otherwise compacted to be contained within the nucleoid. Electron microscopy of ultrathin sections has made it clear that the most general characteristic feature of the structure of the nucleoid is a parallel arrangement of DNA aggregates containing perhaps 500 molecular helices of DNA and preferably oriented to the long axis of the bacterial cell as described by Kellenberger. 50 It seems probable that these aggregates represent DNA fibers folded back and forth. If so, then the question of the postulated contact of the chromosome with the cell membrane is raised. Such contact is demonstrable in electron micrographs, and it is found that in the protoplast there is such a direct contact to the plasma membrane, and in the bacterial cell there is contact, or even penetration, between the nucleoid and invaginations of the plasma membrane (known as mesosomes, plasmalemmosomes, membranous organelles, etc.). It will be recalled in this connection that the nucleoid is not confined within a limiting membrane.

Cytoplasm. 46 The cytoplasm of bacteria appears to have a much less complex structure than that of other cells. The endocytoplasmic reticulum of the usual cell is lacking, particularly in gram-negative bacteria, and the membrane profiles seen in certain gram-positive bacteria are not clearly differentiated. There does appear, however, to be a network of presumably linear arrays with interconnections, and fine fibrils extend from the nuclear plasm deep into the cytoplasm.

Cytoplasmic granules.¹¹ The bacterial cell contains a variety of granules sufficiently large to be seen with the light microscope. Those staining with certain basic dyes are known as metachromatic or Babes-Ernst granules, and are readily observed in bacteria such as the diphtheria and related bacilli stained with alkaline methylene blue or toluidine blue and as polar granules in other forms such as plague bacilli fixed in methanol prior to staining. They are variable in size, to as large as 0.6μ , and larger

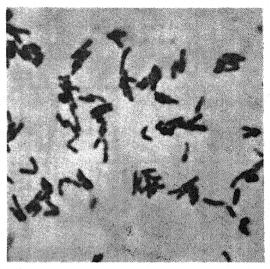

Figure 19. Metrachromatic granules and bipolar staining in the diphtheria bacillus. Note the differences between these organisms and the plague bacilli. Methylene blue: × 1975.

granules may represent aggregates of smaller ones. These granules contain relatively large amounts of trichloracetic acid-insoluble polymetaphosphate whose presence is associated with their metachromatic character. They are dissolved in dilute acid or alkali or boiling water and are characteristically electron-dense but are destroyed in an intense electron beam.

Other visible granules are polysaccharide or lipid in nature. The former stain with iodine to a red-brown color, and the material composing them has been variously termed iogen, granulose, or bacterial starch. Intracellular polysaccharide may also be stained by the periodic acid-Schiff method. Lipid granules have the appearance of vacuoles in bacteria stained with basic dyes but may be stained with lipid-staining dyes such as Sudan III in wet preparations or Sudan Black in dried smears.

The granular polysaccharide and lipid may be regarded as end products of metabolism, and they appear to play no active part in the physiological processes of the cell. Metachromatic granules, however, are the site of enzymatic activity (see below), and the contained polyphosphate serves to store energy conserved in high energy phosphate bonds, accumulated during oxidative processes with adenosine triphosphate (ATP) acting as the intermediate. The term "reserve substance," which has long been

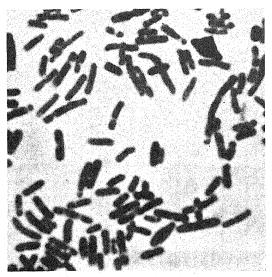

Figure 20. Irregular and bipolar staining of the plague bacillus. Note the heavily stained areas and metrachromatic granules. Fixed in methyl alcohol and stained with methylene blue; × 2400.

applied to metachromatic granules without supporting evidence, acquires significance in this way.

Submicroscopic particulates. In addition to the granules that may be seen with the light microscope, bacterial protoplasm, like that of other cells, contains minute granules or particulates that are separable from soluble constituents of the cell by centrifugation at speeds giving $100,000 \times G$ or more and may be observed only in electron micrographs. It is somewhat disconcerting that such particles are not seen in electron micrographs of ultrathin sections, and it is questionable whether they occur in the bacterial cell in the same form as that found in lysates.

The sedimentation patterns obtained with bacteria disrupted by various means, and exclusive of large fragments such as cell wall, metachromatic granules, and chromatophores, consistently show several distinct macromolecular components. There is usually a broad, slowly moving band at 5 S,* and peaks at 8 S, 20 to 30 S, and 40 S.

The 5 S fraction is a heterogeneous mixture of substances making up the ground material of the protoplasm. The 8 S fraction contains the major portion, 80 to 90 per cent, of the DNA present in the cell. The latter suggests that morphological organ-

*Svedberg units, i.e., S = 10a¹³ cm./sec./unit field.

ization of DNA in the intact cells, as for example in chromatinic bodies or other structures that might be thought to have nuclear organization, is fragile inasmuch as constituent DNA is readily liberated in soluble form. This fraction also contains the unstructured RNA present in the cytoplasm. Together these two fractions constitute the supernatant and contain half or more of the total intracellular substance measured as nitrogen, protein, or dry weight.

RIBOSOMES.66 Of the submicroscopic particulates, the ribosomes have been of special interest since they are intimately concerned with protein synthesis. The cytoplasmic RNA present in the bacterial cell is separable into three kinds on the basis of function, viz., ribosomal RNA (r-RNA), amino acid transfer, or transfer, RNA (t-RNA), and messenger RNA (m-RNA), and these are also differentiable with respect to composition and molecular weight. Further subdivision may be made which does not concern us here. The nucleoid contains DNA's that are complementary in nucleotide sequence to all three kinds of RNA, and these RNA's are synthesized on these templates, r-RNA and t-RNA continuously, and m-RNA at a variable rate depending upon the presence of repressors or inducers with a maximum rate of about one copy site in two to three seconds.

The r-RNA is complexed with protein and presumed to occur in the cell as the 70 S fraction, though particulates of this size have not yet been observed in electron micrographs of ultrathin sections. There appear to be about 12,000 such ribosomes per cell the size of coliform bacilli. The protein moiety has a molecular weight of about 25,000 and constitutes about one-third of the complex. The 70 S complex is separable into two fractions having sedimentation coefficients of 30 S and 50 S, but the significance of this is uncertain.

The function of ribosomes in protein synthesis is dependent upon the function of the two other kinds of RNA which are, for the most part, soluble and present in structureless form in the cytoplasm. There are many kinds of t-RNA in that there are one to four kinds for each of the 20 amino acids. The amino acids are activated by a specific enzyme, and the residue transferred to a specific t-RNA. The m-RNA functions as the template for protein synthesis,

i.e., determines the order of amino acids in the peptide chain, and there are many different kinds of m-RNA, each corresponding to a specific protein. Operatively the appropriate t-RNA-amino acid complexes associate with the predetermined sites on the m-RNA template on the ribosome, each amino acid residue being brought into place by its t-RNA and displacing the previous t-RNA as the peptide chain grows.

Ribosomes occur, presumably in the cell, as aggregates of the 70 S particle (polysomes, polyribosomes) in variable number and linked by strands of m-RNA. This has been taken to indicate that a 70 S ribosome becomes attached to one end of an m-RNA. and progresses along its length as successive reactions with t-RNA's put into place in the peptide chain the amino acids dictated by the m-RNA template and the peptide chain is synthesized. Additional ribosomes may become attached to the same m-RNA, to give continuous synthesis of peptide in various stages of completion at the points of ribosome attachment. On reaching the end of the m-RNA, the completed polypeptide and ribosome are released, and the ribosome is again available to any m-RNA.

INTRACELLULAR LOCALIZATION OF ENZYMES^{60, 70}

It can be anticipated that the morphological differentiation of the bacterial cell into subcellular structures, both at microscopic and submicroscopic levels, may be associated with a corresponding physiological differentiation and biochemical organization. In fact the simultaneous occurrence of opposing processes, such as the synthesis, utilization, and destruction of nucleotides, within the cell makes some effective separation of metabolic processes inevitable.

The external cell structures, flagella and capsules, have no biochemical function, and their loss does not affect the physiological processes of the cell. The flagella serve only as macromolecular muscles so far as is known, and the capsular substance is a product of metabolism shed into the immediate environment, functional only insofar as it provides protection to the cell from, for example, phagocytosis.

Similarly, the cell wall seems to be largely a supporting structure that contributes in a

minor way to the osmotic barrier, but which also may be dispensed with in that the protoplast is physiologically complete with certain exceptions such as its inability to initiate sporulation. Cell walls washed free of protoplasmic contaminants, as judged by electron micrographs, have not been shown to have enzymatic activity.

The plasma membrane, as the most important element in the osmotic barrier of the bacterial cell, is closely associated with enzymatic activity. The intact membrane gives a positive Feulgen reaction as noted above, and the cytochrome system occurs in close proximity to it.

As noted elsewhere, the relative impermeability of the living bacterial cell to substances such as phosphate, coupled with the vigorous metabolic activity of these microorganisms, implies a highly effective transport mechanism across the osmotic barrier. If, as has been suggested, such a mechanism involved the adsorption of nutrient substances and desorption of end products of metabolism by the appropriate enzymes functioning as carriers, the association of enzymatic activity with the membrane would be very close even though the membrane itself may not have activity. Thus, it is plausible to assume that reduction of the cytochrome-cytochrome oxidase system occurs, at least in part at the periphery of the cell organization.55 Further, the facility with which electron-dense particles are trapped in fragments of cell walls of disrupted bacteria suggests that some of these particulates may lie in close proximity to the periphery of the cell.

Further evidence for the localization of enzymatic activity at the cell periphery is provided by, for example, the diffusion of glutamic acid into the cell and the association of glycolytic mechanisms with the cell surface. Glutamine penetrates the cell rapidly while glutamic acid does not unless a source of energy such as glucose is available, implying that the mechanisms of assimilation against a concentration gradient may involve decarboxylation at the cell surface. Similarly, the phosphorylation of hexose by yeast cells appears to occur largely at the periphery of the cell, and the enzymes catalyzing the dephosphorylation of adenosine diphosphate and inorganic pyrophosphate are localized there.

There appears to be little doubt that the

microscopic polymetaphosphate-containing metachromatic granules serve as a source of energy in high-energy phosphate bonds, but the way in which the energy available in these discrete "power houses" is tapped for endothermic metabolic reactions is unknown other than that it is released by way of ATP.

Treatment with tetrazoles, such as triphenyltetrazolium chloride, results in reduction to insoluble formazan which is seen to accumulate in localized areas. Similarly, indophenol blue appears in localized areas following treatment of the cell with the Nadi reagents, α -naphthol and dimethyl-pphenylenediamine. It has been objected that formazan accumulates by accretion in any case, and that indophenol blue may accumulate by solution in lipid granules, so that the granular loci of the indicated activities is an artifact. This criticism is not applicable to the observed sequential color changes in Janus green B which are typical of the mitochondrion and occur in intracellular bacterial granules or, though more slowly, in free granules present in bacteriophage lysates. While, then, these bacterial granules may not be mitochondria, there is evidence that they are the sites of enzymatic activity.

The greater part of the enzymatic activity of the bacterial cell is associated with the submicroscopic granules, and with the soluble substances, i.e., <20 S, present in the ground plasm. The particle size range is broad, although the bulk of the material occurs in the 40 S (10 to 20 m μ) fraction, but there appears to be no definite relation between size and localization of kinds of enzymatic activity. It is possible that the larger particles are aggregates, and the smaller particles fragments, of the 40 S fraction, i.e., the activity of even microscopic granules may be in part a consequence of the presence of occluded submicroscopic particles, while sedimentable enzymatic activity may be solubilized by treatment of sediments with sonic oscillation. Within these implied reservations, kinds of enzymatic activity may be localized in sedimented particles and in supernatant which is assumed to represent ground plasm of the cell.

Components of the electron transport mechanism, including cytochromes and flavin pigments, cytochrome oxidase, DPN-cytochrome c reductase, and DPNH (reduced DPN) oxidase are present in large

part, and possibly almost exclusively, in the submicroscopic particulates. The enzymes functional in the tricarboxylic cycle. however, are found to be divided between sedimentable particles and the ground substance of the cell. Of these, succinic dehvdrogenase occurs almost exclusively in the granules, and 90 per cent or more of the total activity of the cell may be so accounted for. Malic dehydrogenase is found in both granules and supernatant, while aconitase and isocitric dehydrogenase occur exclusively in the supernatant. The localization of α ketoglutaric dehydrogenase is uncertain. Pyruvic dehydrogenase is also found in the supernatant, but the system linking it to O₂ is in the granules. In the catalysis of some of the physiological activities, then, there is a synergistic relation between the granules and the ground plasm of the cell.

The submicroscopic granules emerge as biochemically complex structures capable of carrying out electron transport as well as the oxidation of organic acids at rates substantially equivalent to those reached by the intact cell. It follows that the components, including cofactors, of the catalytic systems are not only present, but present in physiologically available form, and the individual activities are oriented to give an organization having maximal activity. Thus the submicroscopic particle is an integral basic unit of the cell structure and organization, with a firmly established role in oxidative phosphorylation, 16 and is perhaps the bacterial equivalent of the mitochondrion of larger animal cells. Quantitative considerations suggest that the granules may be enzymatically heterogeneous. Assuming a diameter of 20 m μ , a specific gravity of 1.2, and protein to about one-third of the wet weight, such a particle could contain about 14 protein molecules with an average molecular weight of 35,000. It is difficult to reconcile such an estimate with the known presence of a complete electron transport mechanism and succinoxidase system. If there are enzymatically different kinds of granules, they are not separable by differential centrifugation.

COLONIAL MORPHOLOGY OF BACTERIA

When bacteria are grown on the surface of a nutrient medium solidified with agar or

gelatin, the proliferating cells remain approximately fixed in position and form masses of many millions of cells that are visible to the naked eye. The colonies so formed range from a minute, barely visible size to masses several millimeters in diameter. They have characteristics, not only of size, but also shape and texture, and in some instances color, which, while dependent upon the nature of the culture medium and the conditions of incubation to an appreciable degree, under controlled conditions are constant and often of considerable differential value. Colonial morphology is, then, one of the morphological characteristics of bacteria, and one that is indispensable in primary isolation.

The size of bacterial colonies is, assuming favorable cultural conditions, quite uniform within species or type. Streptococcus colonies are, for example, relatively small, 1 mm. or less in diameter, as are those of most types of the closely related pneumococcus, while those of staphylococcus and enteric bacilli are somewhat larger, and those of Bacillus species may be several millimeters in diameter. Minute, dwarf, or D, colonies, much smaller than usually observed, may occur but represent a variant not usually encountered.

The shape of the colony is determined by its edge and by its thickness. The edge may be smooth, or it may be irregular and serrated to a greater or lesser degree. When the thickness is much greater in the center,

diminishing uniformly to the edge, the colony is said to be raised, occasionally so much so as to approach a hemispherical form. Or it may be relatively uniform so that the colony appears to be little more than a disk on the surface of the medium.

The consistency and texture of the mass of cells are also distinguishing features of colonial morphology. The former ranges from the extreme of a dry, friable nature, such that when the colony is touched with a sterile wire it can be pushed about on the surface of the medium, to a viscous consistency so that the cell mass clings to the wire with which it is touched, stringing away from the colony when it is withdrawn. The surface of the growth may be uniformly smooth and glistening, or it may be striated with indentations, radial or concentric, continuous or broken. On examination with transmitted light, the cell mass may appear as amorphous or granular in texture and varies from almost complete translucency, with perhaps a bluish cast, through varying degrees of opalescence to a white or yellowish opacity.

Pigmentation is more common among the saprophytic bacteria, and the cell mass may appear red, orange, yellow, etc., because of the presence of carotinoid pigments, and green in the case of some of the photosynthetic bacteria containing bacteriochlorin. Of the pathogens, the only important pigmented form is *Staphylococcus aureus*, whose colonies are a golden-yellow in color.

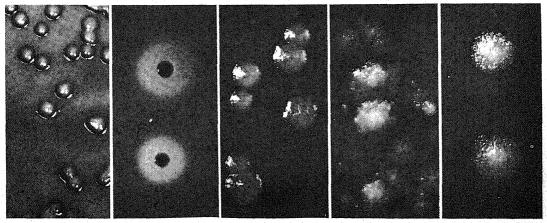

Figure 21. Morphological types of bacterial colonies. From left to right, the raised, smooth, viscous colonies of the gonococcus on chocolate agar; β -hemolytic streptococcus colonies on blood agar showing the cleared zones of hemolysis and the slightly matt, slightly irregular edge of the typical colony; colonies of the typhoid bacillus on nutrient agar, showing the typical irregular edge (maple leaf appearance) and irregular but smooth surface; colonies of the tubercle bacillus on Löwenstein's medium showing the characteristic roughened appearance; and colonies of the anthrax bacillus on nutrient agar in the typically rough, virulent form.

Pigmentation is not apparent in the individual cells for the pigment occurs in intracellular granules too small to be resolved with visible light.

Since these characteristics occur in varying degree and combination from one kind of bacterium to another, colonial appearance is often quite characteristic, and kinds of bacteria may be differentiated from others in mixed or contaminated cultures. Differentiation on the basis of colonial morphology has hardly more than tentative status, however, and detailed study of the physiological and immunological characteristics of a bacterium is ordinarily required for identification.

Colonial morphology is analogous to a statistic in that it is derived from the individual cells but is a characteristic of the cell mass. Thus, pigmentation is apparent not in the individual cell but in the colony; the vicous consistency of the colony derives from the capsular substance of heavily encapsulated bacteria; the coiled texture of Bacillus colonies is a consequence of the tendency of the cells to remain attached end to end and form filaments; actively motile bacteria, such as Proteus, actually move or swarm over the surface of the medium to give a continuous film of growth, etc. In this way colonial morphology may be associated with other significant characteristics of the bacterium, for example, among the pathogenic bacteria virulence may be associated with capsule formation, and when this is true the colony of the virulent form is smooth in appearance and texture, and that of the avirulent form is rough (Chap. Seven).

Colonial characteristics may be accentuated or induced by cultivation of the bacterium on so-called differential culture mediums which exploit relevant physiological properties. When bacteria are grown on an agar medium containing defibrinated blood, areas of greenish discoloration or clear zones in the red opaque medium appear aound the colonies of bacteria which form hemolysins which lyse the erythrocytes and metabolize the hemoglobin to greenish or colorless compounds; such bacteria are said to be α - or β -hemolytic respectively. The ability of diphtheria bacilli to reduce tellurium salts gives rise to black colonies on tellurite differential mediums. Similarly, a sugar such as lactose may be incorporated in the medium together with an indicator such as Schiff's reagent or an acid-base indicator, so that the bacteria fermenting the sugar restore the color to the decolorized fuchsin and the colonies are red or are colored by the indicator because of the local concentration of acidity in the colony. Colonial morphology on such mediums is almost invariably a special case in that the medium is devised to enhance or induce a colonial appearance characteristic of the bacterium in question in order to facilitate its isolation from other bacteria in mixed culture.

The Morphology of Rickettsiae and Viruses

The microorganisms known as rickettsiae and viruses are set apart from the true bacteria, the Eubacteriales, on a physiological rather than a morphological basis. With rare exceptions, the bacteria are not primarily intracellular parasites, and are able to proliferate on lifeless nutrient mediums. In contrast, the rickettsiae and viruses grow only in close association with living ' host cells and are found within the cytoplasm or nucleus. While the largest of these forms link them in continuous series with the smallest bacteria, with progessive decrease in size these agents become distinct both morphologically and in chemical composition.

THE MORPHOLOGY OF RICKETTSIAE

The rickettsiae are morphologically similar to the smallest bacteria. They are coccobacillary to bacillary in form, $0.3~\mu \times 0.3$ to $0.5~\mu$ and occasionally as long as $2~\mu$, and overlap in size range minute bacteria such as Pasteurella tularensis and Bartonella. They are, therefore, demonstrable with the light microscope. They are uniformly gramnegative and stain poorly or not at all unless the dye solution is buffered and mordants are used. In smears and tissue sections they stain purple with Giemsa. In smears stained

by Macchiavello's method (buffered fuchsin, citric acid solution, and methylene blue counterstain) the rickettsiae are red and tissue cells blue, and the buffered methylene blue-safranine counterstain method of Castaneda stains them light blue on a pink background. They also may be stained with diluted Wright's stain following methanol fixation.

They occur singly and in pairs, and most commonly in dense intracellular masses, rickettsiae of the typhus group characteristically in the cytoplasm and those of the spotted fever group in the nucleus of the host cells, particularly those of mesothelial origin which line the serous cavities. They are nonmotile and do not form spores.

The protoplasm stains homogeneously, but Feulgen-positive granules similar to those found in bacteria occur, and both DNA and RNA are present in the cell. In electron micrographs a capsular outer layer, limiting membrane, and electron-dense granules are apparent. In thin sections of Coxiella burnetii the limiting membrane is 5 to 10 m μ thick, and appears to resemble closely the cell wall of bacteria in morphological and chemical properties.^{2, 91} The cell contains a relatively large electron-dense

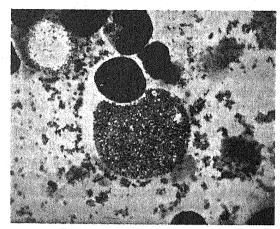

Figure 22. Rickettsiae of Q fever in a smear of skin exudate. Note the macrophage packed with enormous numbers of rickettsiae. × 1125.

body in addition to granules.¹⁰² On treatment of typhus rickettsiae with ether to liberate soluble antigen, the capsular substance is removed and probably represents this antigen.

While the structure of the rickettsiae has not been subjected to as intensive study as has that of the bacterial cell, it seems clear that these microorganisms are closely similar to bacteria, and their physiological char-

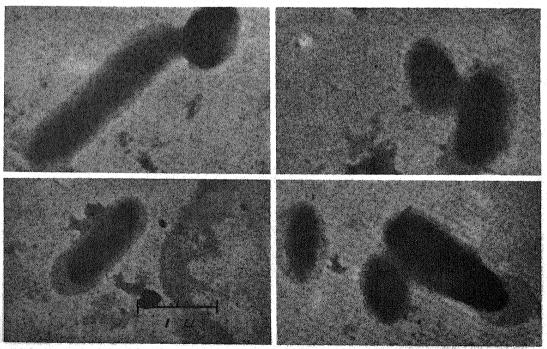

Figure 23. Electron micrographs of typhus rickettsiae from egg yolk culture. Note the variability in size, ranging from coccobacillary to bacillary forms, and the capsular material surrounding the individual cells. (Lilly Research Laboratories.)

acter is not reflected in significant differences in morphology. Since they are not cultivable on lifeless mediums, they have no colonial morphology to correspond to that of the bacteria, but the closely packed aggregates in which they occur within the host cell are suggestive of the viral inclusion body (see below).

While the rickettsiae are incapable of proliferation apart from the host cell, they contain both oxidative enzymes and transaminases. The typhus rickettsiae metabolize glutamate to oxalacetate by way of the scheme

 $\begin{array}{c} \text{glutamate} \rightarrow \text{ketoglutarate} \rightarrow \text{succinate} \rightarrow \\ \text{fumarate} \rightarrow \text{malate} \rightarrow \text{oxalacetate} \end{array}$

and both this mechanism and that of transamination between glutamate and oxalacetate are closely similar to, if not identical with, those found in bacteria (Chap. 5) and higher animals, but these forms lack the enzymatic equipment necessary for independent existence.

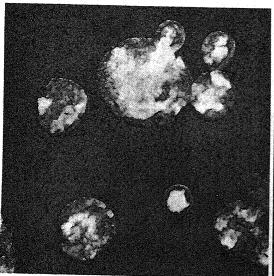

THE PSITTACOSIS— LYMPHOGRANULOMA VENEREUM ORGANISMS^{74, 75}

These agents were long considered to be viruses because of their dependence upon

host cells for multiplication, and cultivation in vitro only in tissue culture. The group includes the causative agents of disease in man, such as lymphogranuloma venereum and trachoma, psittacosis and ornithosis in birds and transmissible to man, and those producing pneumonitis in rodents and diseases of domestic animals such as bovine enteritis and encephalitis.

It has become increasingly clear that these agents are to be distinguished from the viruses, or "true viruses." They contain both DNA and RNA, they are enclosed within a cell wall which is closely similar in its properties to those of bacteria, binary fission appears to be a part of the growth cycle, and the diseases they produce are susceptible to chemotherapy with sulfonamides and many antibiotics. Sensitivity to chemotherapeutic agents is taken to indicate some degree of metabolic independence, and it has, in fact, been shown that these organisms synthesize folic acids and exhibit certain nutritional requirements separable from those of the host cells in which they are cultured.

The morphological character of these agents is complicated by the occurrence of virus particles of two sizes. One, the elementary body, is a sphere about 250 m μ in diameter. In electron micrographs these particles appear as collapsed sacs containing a dense central body apparent as a raised

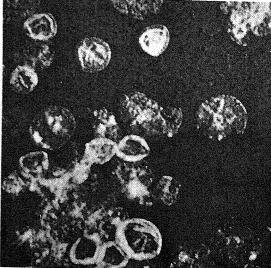

Figure 24. Morphology of microorganisms of the psittacosis group. Left, chromium-shadowed air-dried preparation of the meningopneumonitis agent. The two kinds of particles, relatively large with no central body and relatively small with a dense central body, are apparent. × 20,000. area in the flattened membrane when the preparation is shadow-cast, and larger, 300 to 450 m μ in diameter, because of the flattening. These particles are taken to represent the infectious agent, probably a resting stage, although a single particle is not sufficient to produce infection.

On inoculation into susceptible tissue, larger bodies known as initial bodies appear after some hours. They are 650 to 800 m μ in diameter and are assumed to be swollen elementary bodies. The structure of these particles is unknown. Still larger bodies, sacs or vesicles, may be found in infected cells and tissues, but these have no distinctive morphology.

THE MORPHOLOGY OF VIRUSES

The viruses, or "true viruses," are set apart from the bacteria, not only because of the exceedingly small size of some of them, but more precisely by their content of only one kind of nucleic acid, DNA or RNA but apparently not both, by their reproduction solely through their nucleic acid, and by the inability of the virus particle to grow or undergo binary fission.

Inclusion bodies. They are replicated only within the host cell, utilizing the intracellular synthetic mechanisms of the cell for the synthesis of viral substance. Virus particles may often, though not invariably, be found in masses or aggregates within the cell, demonstrable by light microscopy and known as inclusion bodies.

Inclusion bodies are divided into two groups on the basis of their location within the cell. The inclusion bodies of the pox group of diseases (variola, vaccinia, fowl pox, etc.), myxomatosis, etc., are found in the cytoplasm of the infected cell. Those associated with other virus diseases are characteristically intranuclear, and are of two kinds. One, designated type A, is a relatively large body which disrupts the structure of the nucleus and is found in cells infected with viruses such as herpes, varicella, and pseudorabies. The other, type B, found in a few virus diseases including poliomyelitis, is much smaller and occurs in an otherwise normal-appearing nucleus.

In some instances inclusion bodies have been named after the workers who des-

cribed them, such as the Guarnieri bodies of variola and vaccinia, and the Negri bodies of rabies. Their presence contributes significantly to the characteristic histopathology of a number of virus diseases. For example, while the rabies virus produces inflammatory and degenerative changes in the central nervous system, especially in the spinal ganglia, the disease may be diagnosed with confidence only by the demonstration of Negri bodies present in the cytoplasm of the large ganglion cells in stained impression smears or tissue sections, preferably of the hippocampus major or cerebellum.*

In at least some instances cytoplasmic inclusion bodies are aggregates of infectious units or virus particles and may be considered as analogous to the bacterial colony. This was unequivocally demonstrated, first with fowl pox, in the now classic study of Woodruff and Goodpasture. When the inclusion body is teased apart, it breaks up into minute granules, 200 to 300 m μ in diameter in the case of the poxviruses and those of the psittacosis group, that may be shown to be the infectious unit of the virus. Various names have been given them in the past such as the Paschen bodies of variola and vaccinia, LCL† or initial bodies of psittacosis, or, more generally, elementary bodies. Such terms, with the possible exception of the last, have tended to drop out of common usage, and the infectious virus unit is commonly called the virus particle, or simply virus.

In other virus diseases such aggregates of infectious units are not demonstrable, and the virus particles are liberated by dissolution of the host cell structure, or in the absence of degeneration are shed into the environment in some other way, in some instances possibly by a process of extrusion.

It is not established that all inclusion bodies found in virus diseases are aggregates of virus. On the contrary, the nature of many inclusion bodies, and intranuclear inclusions in particular, is open to question.

The virus particle. As indicated earlier, the virus particle is extremely small, these

^{*}Failure to find Negri bodies cannot be taken as evidence of the absence of infection with rabies virus. The laboratory diagnosis of this and other virus diseases is described specifically in connection with the diseases.

[†]So-called because they were described independently, and practically simultaneously (1930), by Levinthal in Germany, Coles in England, and Lillie in the United States,

microorganisms ranging in size from the largest, the poxviruses, which are about 200×300 m μ and barely resolvable by light microscopy, to the smallest, such as poliovirus, which are about 25 mµ in diameter. The size range is thus about twentyfold, and the size of the mature virus particle is quite uniform, more so than that of the bacteria which grow as individuals and multiply by binary fission. The particles occur in various shapes, including the brick shape of the poxviruses, the rod-shaped forms of a number of the plant viruses, and the more elaborate tailed structure of bacterial viruses, but a great many appear as approximate spheres. In general, the viruses are characterized in terms of chemical composition and physical structure.

Chemical composition.⁵² It has been possible to prepare a great many viruses in sufficiently purified form to allow chemical analysis with some confidence. The viral particle contains nucleic acid, to perhaps 4 to 6 per cent, which is either DNA or RNA but not both. The presence of only one kind of nucleic acid sets the viruses sharply apart from other organisms, and the occurrence of one or the other type of nucleic acid provides the basis of a primary separation of the viruses into two groups, i.e., the DNA viruses and the RNA viruses.

The viral protein is grossly conventional in composition, or tends to show a preponderance of dicarboxylic amino acid residues in contrast to the basic protamineand histone-containing proteins making up the protein moiety of the usual nucleoprotein. Carbohydrate appears to be a viral constituent of secondary importance, though it may lend immunological specificity to viral antigens. The lipid content of viruses varies widely, ranging from 1 to 2 per cent in papilloma virus to 50 per cent reported to occur in equine encephalomyelitis virus, with viruses such as influenza and herpes falling in between with lipid contents of about 25 per cent. The presence of etherextractable lipid may or may not be associated with activity. In general, viruses are either ether-sensitive, i.e., are inactivated by extraction with ethyl ether, or etherresistant, and this property makes possible a useful separation of the viruses into the two groups.

<u>Structure</u>. The developments in electron microscopy, with continued improvement in fixing and staining methods, and the devising of techniques such as negative staining,⁴³ coupled with x-ray diffraction studies, have made possible the elucidation of at least the major elements in the physical structure of the virus particle.

In a general way, virus particles consist of a central aggregate of nucleic acid surrounded by a protein coat, and in some cases an outer membrane which may be single or double. A terminology of the differentiable components of the particle has become generally accepted²² and is most efficiently described as definitions: The protein shell

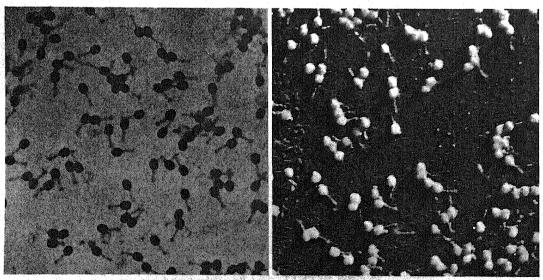

Figure 25. Electron micrographs of coliphage. The plate on the left shows untreated phage, and that on the right a similar preparation shadow-cast with chromium. (Sharp, Taylor, Hook, and Beard.)

surrounding the central core of nucleic acid is known as a *capsid*. The capsid is made up of *structural units* which are assembled in morphological aggregates known as *capsomeres*. The particle made up of nucleic acid enclosed within a capsid is designated a *nucleocapsid*. The outer membrane, which may or may not be present, is the *envelope*. The mature virus particle is a *virion* which may be either a nucleocapsid or a nucleocapsid enclosed in an envelope.

Information concerning the physical organization of nucleic acid in the central core is scant. In some viruses, such as poxviruses, the nucleic acid appears to occur as nucleoprotein, while in others, such as herpesvirus, as nucleic acid alone. Available evidence suggests also that the nucleic acid is present as one molecule, and that this is folded to produce packets in situ.

Of the other morphological characteristics of the virus particle, the structure of the capsid has been of greatest interest. 61, 84, 117 Some viruses, such as adenoviruses, may be found in orderly arrays of virus particles in masses within the host cell, and others, such as poliovirus, not only show such arrays but have been prepared in crystalline form. Such orderly arrangements reflect a symmetrical structure of the capsid and orientation of its component capsomeres. As Crick and Watson²⁶ pointed out in their prediction (1956) of a polyhedral structure of small viruses, the coding of small identical protein molecules would constitute a highly efficient use of the limited genetic information contained in the viral nucleic acid.

Symmetry. Theoretical considerations²³ indicate that the most efficient designs of a protein shell are helical tubes and icosahedral shells, the latter embodying the same principles of geometric design as those of the geodesic dome structures of Buckminster Fuller. It has been found that many, though not all, viruses show helical or cubic symmetry; obvious exceptions include the poxviruses and bacterial viruses.

Of the viruses showing helical symmetry, many are plant or insect viruses, and of these perhaps the best known is the tobacco mosaic virus. As described below, the capsid of this virus is a hollow tube of protein in the form of a helix, and made up of 16½ subunits per turn. Certain animal viruses, notably myxoviruses, also have helical symmetry though this is less overtly obvious

since the particles are roughly spherical in shape. The helical component of influenza virus, for example, appears to be tightly wound or packed within an envelope. It is not seen in the usual preparations, but in partially disrupted particles is found in whorls and parallel strands.

The usual type of viral cubic symmetry is icosahedral, and many of the animal viruses, including poliovirus, herpesvirus, reovirus, adenovirus, and polyoma virus, fall into this group. Such symmetry is the basis of the structure of the capsid, but the virus particles need not conform precisely to this shape. Such viruses fall into classes with respect to the number of capsomeres making up the capsid, viz., 12, 32, 42, 92, 162, 252, and 812. Formulas have been presented for the calculation of the number of capsomeres, and the general formula of Wildy and Horne is $10x(n-1)^2+2$ where x may have a value of 1 or 3, and n is the number of capsomeres between and including those on adjacent five-fold symmetry axes.²³ There is reason to believe that the icosahedral capsids are constructed with two kinds of capsomeres, the one pentagonal and containing five asymmetric units, and the other hexagonal and made up of six asymmetric units. For example, adenovirus types 2 and 5 have 252 capsomeres, of which 12 pentagonal capsomeres are on the vertices, and 240 hexagonal capsomeres on the edges and faces.

In addition to the capsid, and envelope if present, other structures, demonstrable by negative staining for the most part, may be found in a number of kinds of virus particles. The Poxvirus particles, for example, have been found to contain diagonal tubular structures in irregular pattern, and influenza virus particles have a surface (envelope) structure characterized by regular projections. The nature of these and other components of the virus particle are as yet only poorly understood in terms of chemical composition, antigenicity, function, etc. 79, 113, 118

THE BACTERIAL VIRUSES (BACTERIOPHAGES)1, 3, 20, 99, 100

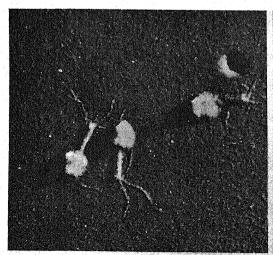

Transmissible lysis of bacteria was discovered by Twort in 1915 and rediscovered by d'Herelle in 1917 and for many years was known as the Twort-d'Herelle phenom-

enon. The agent is present in bacteria-free filtrates of lysed cultures of bacteria, and the addition of such filtrate to a fresh, growing culture results, after a suitable period of incubation, in lysis manifested as a clearing of a broth culture, or a cleared zone, or plaque, in a uniform film of bacterial growth on the surface of an agar culture medium. This phenomenon is a consequence of the activity of viral agents parasitic on bacterial cells. There are very many of these bacterial viruses, or bacteriophages, some broadly specific and others narrowly specific, even within species, for the host bacteria.

Since the bacterial viruses are readily manipulated in the laboratory, they have served as prototypes in the investigation of the nature of viruses, although it does not follow that they are directly comparable in all respects with animal and plant viruses. Consequently, they are better known than most of the other viruses, and of the bacterial viruses a group parasitic on coliform bacilli have been by far the most intensively investigated. There are seven of these "T" strains in all, of which T2, T4, and T6, the "T-even" phages, constitute one serological group, T_3 and T_7 another, while T_1 and T_5 are unrelated to one another or the other T-coliphages. All of these are tadpoleshaped, as are other phages which have been examined critically, but the tails of T₃ and T₇ are very short. Phages parasitic on other bacteria, including staphylococci, streptococci, and mycobacteria, also appear to have this same general type of morphology. 12

In electron micrographs of freeze-dried preparations of the T-phages, the heads are polyhedral, almost crystalline, in form and, when observed either parallel or perpendicular to the tail, have six relatively linear sides. The heads of the T-even phages are elongated hexagons, 65×95 m μ , while the other T-phages have hexagonal heads, ranging in size (diameter) from 47 mu for T₃ and T_7 , through 50 m μ for T_2 to 65 m μ for T₅. The tails vary in size and proportion; those of the T-even phages are $100 \times 25 \text{ m}\mu$, those of T_1 and T_5 are more slender, $150 \times$ 10 m μ and 170 × 10 m μ respectively, while those of T3 and T7 are stubby and measure 15×10 m μ . The tail is not an organ of locomotion, for it does not contribute to the rate of diffusion of the phage, i.e., while the rate of adsorption on bacterial cells is proportional to the cell concentration, it is considerably less than the calculated collision rate and therefore not consistent with the assumption that the bacteriophages are actively motile.

The phages are DNA viruses, though RNA phages have been described. ¹²¹ Detailed study has made it clear that the phage particle is a differentiated, relatively complex structure. The head portion is made up of DNA, ⁸ making up as much as 40 per cent of the virus particle as noted above, enclosed in an envelope or membrane of protein. The latter apparently has some function as an

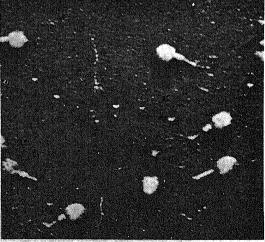

Figure 26. The structure of the distal portion of the tail of the T-even coliphages. Left, T₄ frozen and thawed to free the protein strands. × 100,000. (Williams.) Right, the protruding tail spike of T₂ coliphage apparent after removal of the distal tail protein by treatment with peroxide. × 100,000. (Kosloff.)

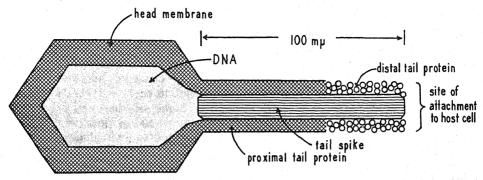

Figure 27. Schematic representation of the differentiated structure of coliphages of the T-even series.

osmotic barrier for, when the particle is subjected to osmotic shock, the DNA leaks out to leave an empty shell.²⁹

The tail structure is also complex, the component parts playing different roles in the first stage of the reproductive cycle in which the phage particle is adsorbed at the tip of the tail onto the surface of the bacterial host cell (Chap. Four). The tail appears to be a tubular structure closed by a plug or tail spike. In the T-even and certain typhoid bacillus phages, the tail sheath is contractile, but in other phages it is not. The distal portion of the tubular structure is differentiated from the proximal portion in that the last few m μ are made up of protein strands held together by a thiol ester linkage. It may be depolymerized by treatment with Zn⁺⁺ or Cd⁺⁺, and is depolymerized following adsorption onto the host cell, in both instances leaving a portion of the tail spike uncovered. In addition, the extreme tip of the tail is differentiated, apparently with respect to the distribution of positively charged amino groups that play an essential part in the initial absorption.

Serological studies have shown that at least two immunologically distinct proteins are present in the phage particle, the one in the head membrane and the other in the tail; antibody to the tail portion is that which neutralizes phage infectivity. It is clear that at least four distinguishable proteins are present, viz., that of the head membrane, that of the proximal portion of the tail, that of the distal portion of the tail, and that of the tail spike.

The formation of areas of bacteriophage

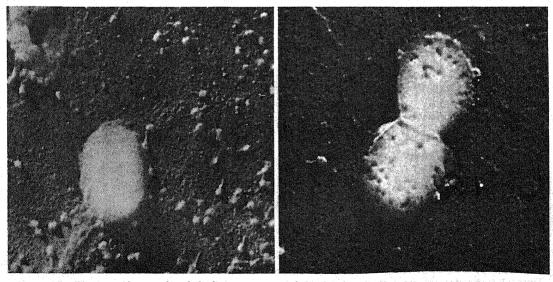

Figure 28. Electron micrographs of shadow-cast preparations showing the lysis of coliform bacilli by coliphage T_4 . Left, an intact bacillus surrounded by phage particles; right, a bacillus about to undergo fission from which the cell membrane has begun to peel away in the initial stage of lysis. \times 20,000. (Wyckoff.)

lysis in the confluent growth of susceptible bacteria on the surface of agar mediums has been noted above. When these are discrete, they are analogous to bacterial colonies in that it is a reasonable assumption that the area is a result of the proliferation of a single phage particle and consists of the progeny of that particle just as the bacterial colony is made up of the progeny of a single viable cell. Such discrete areas of phage lysis are known as plaques. Thus phages may be isolated in "pure culture" by streaking an agar medium previously inoculated sufficiently heavily with susceptible bacteria to give confluent bacterial growth, and the plaques may be picked and "subcultured." The occurrence of phage plaques also makes available an additional morphological character, that of plaque morphology.

While there are not as many variables, and therefore combinations of characteristics, in bacteriophage plaques as in bacterial colonies, the plaques have a distinctive character of differential value. There are, for example, "large plaque" phages, "small plaque" phages, and "minute plaque" phages. Another plaque type is the tu, or turbid halo, type characterized by a clear center surrounded by a diffuse cloudy zone. Or the margin of the plaque may be sharply defined or hazy. These plaque characteristics have the same validity as those of bacterial colonial morphology and may be regarded as phenotypic expressions of genetic character.

ANIMAL VIRUSES4, 18

The animal viruses fall into a number of differentiable morphological types observable by electron microscopy, including examination of negatively stained preparations. Some of these may be considered briefly here, and in more detail in later chapters devoted to individual or groups of viruses.

Poxviruses. The viruses making up the pox group are relatively homogeneous morphologically. The group includes the causative agents of diseases of man such as variola, vaccinia, molluscum contagiosum, and diseases of lower animals such as myxoma and fibroma of rabbits, fowl plague, and mouse pox.

The virus particles are brick-shaped and relatively large, 200×300 m μ , though some may be somewhat smaller. In electron micrographs a dense central portion is apparent. Digestion with pepsin accentuates the appearance of the central body and shows a limiting membrane. Subsequent treatment with deoxyribonuclease results in the dissolution of the central body, leaving the virus particle as an empty membrane. The structural similarities to the bacteria, *i.e.*, a central mass of DNA surrounded by "viroplasm" and enclosed within a single or double limiting membrane, have been noted by many workers.

Myxoviruses. 42 The viruses of this group are RNA viruses, are generally spherical

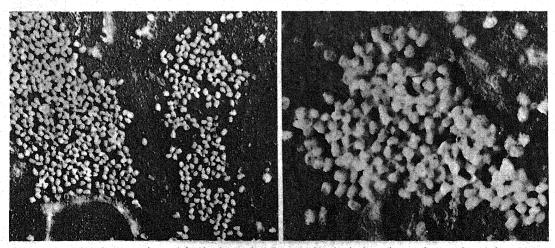

Figure 29. An electron micrograph of thin section through the chorioaliantoic membrane of a 10-day chicken embryo 24 hours after inoculation with vaccinia. The numerous elementary bodies can be seen to possess a cuboidal or cylindrical shape. Left, × 4500; right, × 12,500. (Wyckoff.)

in shape, have helical symmetry, and are ether-sensitive. The nucleoprotein coil is enclosed in an envelope in which host cell constituents, particularly lipids, are found. The outer structure of the particle is readily deformed, leading to variability in observed size. The term myxovirus refers to an affinity for mucinous substances, such as that found on the surface of erythrocytes, where it is functional in viral hemagglutination, and these viruses have an enzyme, neuraminidase, which depolymerizes the mucinous substrate.

These viruses fall into two groups, designated group I and group II, or subgroup I and subgroup II. The viruses of group I are 80 to 120 m μ in diameter, and the nucleoprotein coil has a diameter of about 9 m μ . Group II contains the larger viruses, 150 to 250 m μ in diameter, in which the nucleoprotein coil has a diameter of about 18 m μ . There tends to be some morphological variation, as in the appearance of influenza virus in filaments, and the varied shapes assumed by Newcastle disease virus in particular.

Group I includes the human influenza viruses types A, B, and C, swine influenza virus, and fowl plague virus, while group II is made up of Newcastle disease virus, mumps virus, the parainfluenza viruses, and the simian viruses SV5 and SV41. Some other viruses, such as the Rous sarcoma

virus, measles virus, rinderpest virus, and canine distemper virus, are closely similar morphologically to the accepted myxoviruses.

Herpesviruses. The viruses of this group are DNA viruses, in which the DNA may be double-stranded. They have cubic symmetry, with 162 capsomeres making up the icosahedral capsid, and are enclosed in a double envelope, and the mature virus particle is spherical and 120 to 130 m μ in diameter. The herpesviruses are ether-sensitive.

The group includes the viruses of herpes simplex of man, and B virus, pseudorabies virus, and virus III occurring in lower animals. The varicella-zoster (chickenpoxherpes zoster) virus is somewhat larger, 150 to 200 m μ , and while once thought to be related to the poxviruses, is now considered to be a herpesvirus. There are a number of morphologically similar viruses, such as cytomegalovirus of man, and viruses producing respiratory disease in lower animals, which are regarded as herpes-like, and considered by some to be herpesviruses.

Adenoviruses. These viruses are DNA viruses having an apparent filamentous structure in the nucleoid. They show cubic symmetry, with 162 or 212 capsomeres making up the icosahedral capsid, and are approximate spheres having a diameter of 70 to 80 m μ . The virus particles often appear in orderly arrangement in crystalline-

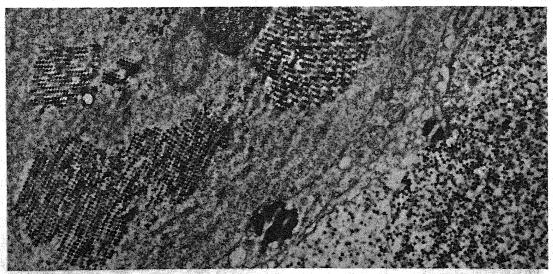

Figure 30. Adenovirus in two adjacent cells. In the cell on the right the virus particles are dispersed at random, but in the cell on the left they occur in ordered arrays, and the latter aggregates may be seen with the light microscope within infected cells. The two kinds of virus particles, the one more electron-dense than the other, are clearly apparent. × 11,550. (Councilman Morgan.)

like cytoplasmic inclusion bodies in infected cells. These viruses are ether-stable.

The adenoviruses of man are also known as the APC (adenoidal-pharyngeal-conjunctival) viruses after the kinds of disease they produce, and are separable into numbered serological types. Closely similar viruses are of simian, bovine, murine, and avian origin. The avian adenovirus is often referred to as GAL (gallus-adenovirus-like) virus. It has been suggested that infectious canine hepatitis virus is an adenovirus.

Picornaviruses.⁸² This is a group of RNA viruses of very small size, 22 to 27 m μ in diameter, which has given rise to the name: pico (small), RNA, virus. The picornaviruses have cubical symmetry, and possibly 42 capsomeres make up the icosahedral capsid. Their content of nucleic acid is relatively high, 25 to 30 per cent, and they are ether-resistant.

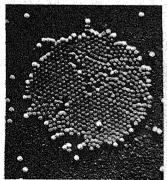

The viruses of human disease in this group include those known as the enteroviruses, i.e., polioviruses, the Coxsackie viruses, the ECHO (enteric cytopathic human orphan) viruses, and the rhinoviruses which are causative agents of the common cold. Poliovirus and Coxsackie type A viruses have been prepared in crystalline form. A number of viruses which are the etiologic agents of disease in lower animals also fall within the group, i.e., the virus of foot-and-mouth disease of cattle, the encephalomyocarditis virus, and that causing Teschen disease of swine.

Papovaviruses. These are DNA viruses, containing double-stranded nucleic acid, and are considered to be oncogenic, or poten-

tially oncogenic. The name derives from papilloma, polyoma, and vacuolating agent, and was suggested by Melnick to meet with general acceptance. In general, these viruses are relatively small, 30 to 50 m μ in diameter, have cubic symmetry with 42, 60, or 92 capsomeres making up the capsid, and have no envelope, but there is some variation, or at least uncertainty, within the group.

The etiologic agent of infectious warts in man is a member of this group, and has been reported to be 45 m μ in diameter, with 42 capsomeres in the capsid, and tends to form crystalline-like aggregates within the infected cells. The rabbit papilloma virus of Shope is also about 45 m μ in diameter, and 42, 60, and 92 capsomeres have been reported. There are a number of other papilloma viruses of lower animals which are not well known but considered to be papovaviruses. The polyoma virus, an oncogenic virus with less marked host specificity, is about 45 m μ in diameter also, and the number of capsomeres has been variously reported as 42 and 92. The so-called vacuolating virus of simian origin, SV40, is also a member of this group, measures 40 mµ in diameter, and has 42 capsomeres making up the capsid.

Arboviruses. The viruses of this group have the common property of being arthropod-borne, hence the name, but in general are much less well known than many other viruses, and may be a heterogeneous group and include viruses which may be found to have other affinities. They are probably all RNA viruses, are ether-labile, and the nucleocapsid is enclosed in a membrane.

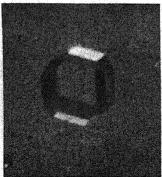

Figure 31. Poliovirus. Left, purified virus, showing the spherical form and tendency of the virus particles to pact together. \times 8000. Center, a crystal of poliovirus. \times 100. Right, the sheared surface of a crystal of the virus, showing the occurrence of the virus particles in orderly arrays. (Schwerdt.)

Their symmetry is uncertain as yet, they are spherical in shape, and they range, from one virus to another, from 20 to over $100 \text{ m}\mu$ in diameter. The majority have been given place names, e.g., eastern, western and Venezuelan equine encephalomyelitis virus, Sindbis virus, Semliki Forest virus, West Nile virus, and Japanese B encephalitis virus, and rarely descriptive names such as Chikungunya virus. There are two types, type A and type B, separable by hemagglutinin character, but apparently not morphologically distinct.

THE INSECT VIRUSES 10, 93, 94, 97, 98

A number of infectious diseases of insects, especially insect larvae, are caused by viruses. The majority of these diseases are characterized by the presence of inclusion bodies in the infected cells, which are made up of virus particles. Sacbrood of bees is exceptional in that inclusion bodies are not found.

Many of these inclusion bodies are polyhedral in shape, ranging in size from 0.5 to 15 μ , but most commonly 3 to 5 μ , and the diseases in which they occur are known as polyhedral disease or polyhedrosis. The best known of these is jaundice of silkworm (Bombyx mori) larvae and has been recognized since the early sixteenth century.

Other insect larvae infected by similar agents are the nun moth, the gypsy moth, and some species of caterpillars.

The other kind of inclusion body is a small oval body, usually less than 1 μ in length, and the associated viruses are sometimes known as the capsule viruses or granulosis viruses. They produce disease in certain caterpillars, cutworms, and butterfly larvae.

The intact inclusion bodies are insoluble in water and are not affected by the processes of bacterial decomposition of the host tissue, so they may be prepared in relatively pure form by centrifugation. They may be dissolved in dilute alkali to liberate the virus particles, and presumably an analogous process occurs in the gut of the insect at the initiation of infection. The inclusion bodies consist of nucleoprotein (DNA type) virus particles embedded in a matrix of protein, which is serologically related to that of the virus particles, and enclosed in a "limiting membrane" of precipitated specific, or closely related, protein. The protein matrix makes up about 95 per cent, and the virus particles 3 to 5 per cent, of the inclusion body.

The particles of the majority of the insect viruses are rod-shaped, 20 to 27×200 to $400 \text{ m}\mu$. It was believed for many years that all the insect viruses were rod-shaped until it was shown that in some instances

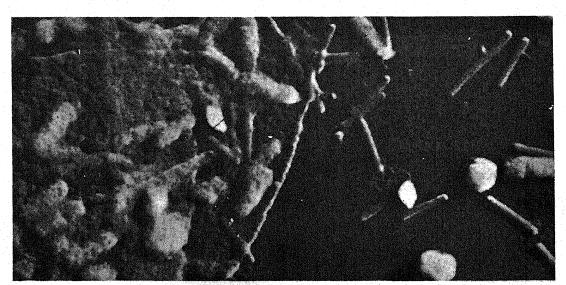

Figure 32. The virus of polyhedral disease of the gypsy moth (*Porthetria dispar*) showing the polyhedral body on the left. The "packets" of rod-shaped virus particles are enclosed within limiting membranes both within the polyhedral inclusion body and outside it, and the rod-shaped particles are those of mature free virus. × 22,000 (Bergold.)

spherical forms, 20 to 40 m μ in diameter, may predominate.

The rod-shaped particles occur in the inclusion body in small aggregates enclosed in a membrane. In the polyhedral inclusion body there may be six to eight individual rods arranged as bundles, while in the smaller oval inclusions single rods predominate, and occasionally two or three may be found within a single membrane. In the intact or disintegrating inclusion body, spheres may be observed occasionally, and there is reason to believe that the rods originate in the spherical bodies, and break down to liberate spheres in a reproductive cycle. Filaments may occur also which are reminiscent of those associated with some of the animal viruses. In its early stages the inclusion body is liquid in consistency, but it becomes more viscous as the protein concentration increases, and finally protein precipitates at the periphery to complete formation of the mature inclusion. In any case, it is probable that the rods represent the resting stage of the majority of these viruses, but in some instances the sphere may be the resting stage.

PLANT VIRUSES⁵⁹

A considerable number of diseases of plants are of virus etiology, and the third group of viruses is made up of these agents, the plant viruses, separable into more than 100 kinds. The diseases they produce include the yellows group of diseases (such as aster yellows); the mosaic diseases of tobacco and acuba; the ring spot diseases of tobacco, potato, and delphinium; the leaf-curl diseases of tobacco, cotton, and sugar beets; the leaf savoy (leaf deformation) diseases of beets and rutabaga; and spotted wilt of tomato.

Almost all of these agents are transmitted by arthropod vectors of the families Aphididae (aphids), Cicadellideae (leaf hoppers), Aleyrodideae (white flies), Coccideae (mealybugs), and Thrysanoptera (thrips). Of these vectors, the aphids are by far the most common, the leaf hoppers less so, and only one plant virus, that of spotted wilt, is transmitted by thrips; the white fly vectors are more common in tropical climates than in temperate climates. While transmission may be mechanical, and usually is for example in aphids, it may also be biological in

that the insect vector is infected, is capable of transmitting the virus only after an incubation period, and may remain infectious for long periods or even for life. In a few instances, such as rice stunt virus, the virus is transmitted from the female to the egg.⁵⁸ Such biological transmission is of particular interest in that it indicates that the range of hosts capable of supporting growth of the virus extends from the plant to animal kingdoms. A number of these viruses have been cultivated in tissue cultures which simulate the insect tissues.³⁵

Some of these viruses have been studied intensively, while others are not so well known. In general, they occur as two morphological types, the one rod-shaped and relatively large and including tobacco mosaic virus (TMV) and cucumber virus, both 300×15 m μ , and the virus of potato-X disease which is a somewhat longer, more slender rod, 430×10 m μ . The remainder of the plant viruses are small spherical or polyhedral particles 15 to 30 m μ in diameter. A number of these viruses, notably TMV and cucumber viruses, and the viruses of bushy stunt of tomato, tobacco necrosis, Southern bean mosaic, and turnip yellow necrosis, have been prepared in crystalline form. These viruses appear to consist of pure, or nearly pure, nucleoprotein. The nucleic acids of the plant viruses are of the RNA type exclusively, in contrast to the bacterial and animal viruses, with nucleic acid contents ranging from 5 to 6 per cent to as high as 40 per cent in the case of tobacco ring-spot virus. Two of the plant viruses, TMV and bushy stunt virus, may be taken, for present purposes, as examples of the better known plant viruses.

Tobacco mosaic virus.^{81,96} This virus, the first to be crystallized, was prepared by Stanley in 1934 as needle-shaped paracrystals. It is a pure nucleoprotein, containing 94 per cent protein and 6 per cent nucleic acid of the RNA type, with a molecular weight of about 5 million.

The infectious unit is a cylinder of protein, 300×15 m μ , with a core of nucleic acid, probably multistranded, about 4 m μ in diameter. The virus may be found in, or broken down to, units of less than this length, and may occur in multiples of it, but the smaller rods do not have virus activity. The rods are deeply grooved and may be packed screw-wise more tightly than the

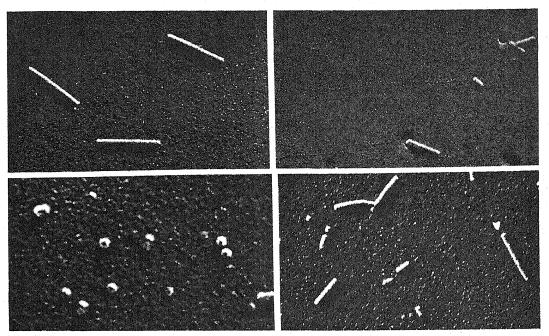

Figure 33. Tobacco mosaic virus. Upper left, the infectious particle of the virus. \times 58,000. Upper right, partially disintegrated virus particles, showing the fine strands of the central core of nucleic acid attached to the fragments. \times 42,000. Lower left, the washer-shaped units of the cylindrical protein structure. \times 115,000. Lower right, "reconstituted" virus, showing the variability in size of the particles so produced. \times 50,000. (Williams.)

diameter of 15 m μ would suggest. The way in which the nucleic acid and protein components are bound is not known, but it is of such a nature that the nucleic acid is not attacked by RNA-ase in the intact particle.

The particle may be broken up by treatment with alkali, sodium dodecyl sulfate, or urea, with separation of protein and nucleic acid, and disintegration of the protein into chemical subunits with a molecular weight of 17,000 to 18,000 in which threonine is the C-terminal amino acid, and the N-terminal is bound in a ring structure. The peptide chain of 145 residues is coiled in the form of a helix so that the subunits have a washer-like form. The minimum size of subunit that can be polymerized to give a rod-shaped structure is, however, larger than this, with a molecular weight of about 100,000.

It has been possible to copolymerize the protein and nucleic acid components after separation in sodium dodecyl sulfate to give rods of the original composition and size and having viral activity. Further, a "hybrid" virus has been prepared by combining nucleic acid from the ribgrass strain of TMV with protein from ordinary TMV to give a virus that produced a disease characteristic of the ribgrass strain and whose progeny contained both ribgrass protein and nucleic acid. The relatively greater importance of the nucleic acid portion of the molecule is further indicated by the production of relatively extensive changes in the protein without affecting viral activity. Thus, activity is not lost when as much as 70 per cent of the free amino groups are acetylated, or all the -SH groups are re-

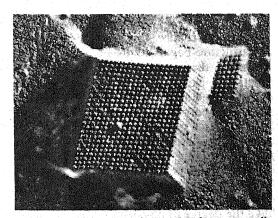

Figure 34. Electron micrograph of an unusually perfect rhombic type crystal of tobacco necrosis virus, prepared by the carbon replica technique. × 42,000. (Labaw and Wyckoff.⁵⁴)

acted with iodine, though inactivation occurs when iodine is substituted in the tyrosine ring. Again, the progeny of such altered virus contain the normal TMV protein component. It is clear that such studies are beginning to approach the goal of some understanding of the nature of viral, or for that matter protoplasmic, replication during the processes of growth.

Bushy stunt virus.²¹ The virus causing bushy stunt of tomato is representative of the smaller spherical plant viruses. It has been crystallized in the form of dodecahedral crystals and is apparently largely, if not entirely, nucleoprotein, but contains considerably more, 16 per cent, nucleic acid than TMV. In electron micrographs of airdried preparations it appears to be spherical in shape and about 30 m μ in diameter. In freeze-dried preparations, it is apparent that the virus particles are polyhedral rather than spheroid in shape and in cross section are usually hexagonal. The virus particles tend to occur in orderly arrays, and the crystals are made up of such arrayed particles. X-ray diffraction studies suggest that the virus particle is made up of 60 subunits with a molecular weight around 125,000.

COMPARATIVE MORPHOLOGY OF MICROORGANISMS

The fungi and animal parasites considered elsewhere are more complex and morphologically conventional than the bacteria in that even the unicellular forms are differentiated into the usual nucleus and other intracellular structures. Beginning with the bacteria, and the blue-green algae not touched upon here, this familiar pattern of cell structure begins to dissolve.

Among the bacteria the existence of a functional, morphologically discrete nucleus becomes nebulous, and its place is perhaps taken by the chromatinic body, containing large amounts of DNA but of no more than equivocal relation to a nucleus. Polyphosphate-containing granules visible with the light microscope occur, but apparently function in the storage of energy in the form of high-energy phosphate bonds, and do not have the degree of physiological competence associated with the mitochondrion of conventional cells. Rather, mitochondrial

function is associated in part with minute intracellular particulates, and quantitative considerations suggest that even these, as individual particles, may not have the metabolic activity they show in the aggregate. The cell wall persists as a supporting structure and may, because of its minor contribution to the osmotic barrier, have survival value, but it may be dispensed with to leave a functional physiological unit, the bacterial protoplast, apparently lacking only the ability to initiate spore formation.

In the size range of the larger viruses the inevitable effects of size become even more apparent in that the differentiated structure that persists serves to house and protect a nucleic acid directive mechanism, and the unit consists of little more than a protective membrane surrounding an electron-dense body consisting, presumably, largely of nucleic acid compounds. Finally, in the simplest viruses there is little or no structure, and the particle consists of naked nucleoprotein that has organizational individuality only indirectly through the directive mechanism it contains and possibly can be considered as "living" only because it can reproduce itself indefinitely in series in a host cell. It is probable that the "living organization" reaches its lower limit at the dimensions of large protein molecules; thus the smallest subunit of TMV that can be polymerized to give an infectious unit has a molecular weight of 100,000, and the subunit of bushy stunt virus has a molecular weight of 125,000. This apparent lower limit in size may be taken to represent that in which the nucleic acid is effectively protected by the protein coat, i.e., that of resting virus. With the demonstration of infectious nucleic acid (Chap. Four), the lower limit may be reduced to that of the size of a macromolecule of polymerized nucleic acid.

Chapter Four

THE GROWTH OF MICROORGANISMS

The growth of microorganisms is essentially the specific, balanced synthesis of the components of protoplasm from the nutritive substances present in the immediate environment. In addition, the newly synthesized constituents must be assembled and appropriately packaged to yield replicates of the original unit. The specificity of the entire process is dependent upon the operation of directive mechanisms, or genetic controls, which have the unique property of self-replication so that they appear as intrinsic parts of the new units.

This complex process is obviously dependent upon, and affected by, the kinds and concentrations of nutrient substances present in available form and upon a continuous supply of energy required for the endothermic reactions of synthesis. The source of the latter is the coupled oxidation-reduction reactions of respiration, so that, in the broad sense, the nutritive environment also includes oxidizable substrates together with reducible substances functioning as immediate and/or ultimate hydrogen acceptors.

Microbial growth may be approached in a number of ways. The most obvious are the cytological approach, that of the growth of microorganisms as population, and that of the nature of the biochemical processes involved. Such separations are artificial in that they represent no more than relative emphasis on one or another view of the same process but are useful for purposes of discussion. The first two will be considered here, and the last elsewhere (Chap. Five).

THE GROWTH OF BACTERIA

By far the most common method of multiplication of bacteria is that of simple binary fission in which the cell apparently constricts and separates into two daughter cells. Fission occurs in a single plane, at a point indicated by the development of a thickened, equatorial band in the cell wall, at a right angle to the long axis of bacillary and spiral forms. It may occur in one, two, or three planes of the spherical forms, making possible the characteristic morphological groupings described earlier (Chap. Three). Bacilli and spirochetes show some elongation prior to fission. The cocci do not, as a rule, although there may be some increase in the diameter of the cell without significant alteration of its spherical form. The size a single cell must reach before fission is quite constant, although differences in this maximum are associated with the age of the culture (see below).

While cell division is clearly intimately related to the synthesis of cell substance, it may appear to be a distinct process in that, within limits, cell division may be inhibited by failure or inhibition of cell wall synthesis, while other components of the cell substance continue to be formed. One of the effects of penicillin, for example, is an inhibition of cell division of staphylococci, and the individual cells continue to grow without dividing and become greatly enlarged. Cell division may be inhibited in a number of other ways as, for example, by culture in magnesium (Mg⁺⁺) deficient medi-

ums, by treatment with certain organic compounds such as 5-diazouracil, acriflavine, or methylenemelamine, or with ionizing radiation such as x-radiation or α -radiation. When rod-shaped bacteria are treated in this way, they fail to divide and continue to grow as long filaments.

More precise definition of the internal structure of the bacterial cell has made more clear some cytological aspects of cell division. 19, 47 The first step is the formation of a septum, or cell plate, across or slightly oblique to the long axis in the case of bacillary forms, dividing the cell contents into approximately equal portions. In gram-positive bacteria this develops by centripetal growth of the plasma membrane, followed closely by the cell wall. The manner in which this occurs is not entirely clear, viz., whether the plasma membrane grows by extension, or whether its formation is associated with the minute peripheral bodies that appear in electron micrographs of ultrathin sections to move inward with the centripetally growing cell wall. In any case, constriction of the cell occurs, and the two daughter cells separate. In the gram-negative bacteria, growth of the cell wall appears to be general rather than local, followed by constriction prior to cell division.

While bacterial multiplication usually takes place by transverse fission, other kinds of cell division may occur. Some, such as the diphtheria and tubercle bacilli show true branching that is characteristic of some of the higher fungi, and budding, similar to the budding of yeast cells, has been described by some workers. More complex processes occur, such as the formation within the cell of viable granules, or gonidia, which on liberation develop into morphologically typical cells; this is firmly established as the so-called swarmer stage in the development of some soil bacteria, but is not otherwise of common occurrence. Another kind of more complex reproductive process occurs in the Bacteroides and Mycoplasma (Chap. Twenty-seven), in which these structurally fragile cells swell to form large round bodies that then may undergo multipolar germination, with segmentation of outgrowing processes to form daughter cells. All these more complex kinds of reproduction are quite uncommon in that they may occur in only a very few kinds of bacteria with some regularity, or extremely rarely in many kinds of bacteria.

Conjugation between bacterial cells of differing sexuality occurs with transfer of genetic determinants (Chap. Seven) but, like spore formation, it is not considered to be a mechanism of replication *per se*.

The generation time in binary fission, *i.e.*, the time elapsing between cell divisions, is minimal during the exponential growth phase (see below) of the bacterial culture. Certain enteric forms, such as the cholera vibrio and coliform bacilli, are among the most rapidly proliferating bacteria, with generation times of 20 minutes or less, and one marine Pseudomonas species has been found to have a generation time as short as 9.8 minutes.²⁵ More slowly growing bacteria, such as the tubercle bacilli, have generation times of several hours, or even days.⁶⁸

The rapidity of cell division among the bacteria is not unique as sometimes supposed, for embryonic cells of higher forms may multiply equally rapidly. The unique aspect of the rate of bacterial multiplication lies, rather, in the fact that such a short time is required for the bacterial cell to reach full maturity.

THE GROWTH OF BACTERIAL POPULATIONS

For obvious practical reasons bacteria are ordinarily manipulated and studied, not as individuals, but as aggregates made up of very large numbers of cells. Bacterial growth may be considered as the growth of populations of many millions of cells whose characteristics are essentially statistical ones, and the behavior of individual cells is assayed as a frequency.

Growth of bacteria in culture may be considered from a number of points of view, and the methods of its measurement depend upon the purpose at hand. A simple view that is commonly, if tacitly, taken assumes that growth may be described by the reaction:

culture medium $+ O_2 \rightarrow$ bacterial protoplasm + oxidized substance

which proceeds from left to right, and eventually comes to an equilibrium. The reaction velocity constants may be determined by the rate of disappearance of the reacting substances or the rate of appearance of end products.

Although complicated by a variety of side reactions, the assumption of such a relation has been extremely useful in studies on bacterial metabolism. The growth of autotrophic bacteria, for example, is conveniently measured in terms of the conversion of carbonate to organic carbon. A somewhat more mechanistic concept is that of the instability of an inoculated culture medium which, after undergoing a series of complex changes, reaches a stable equilibrium at a lower energy level and provides the basis of studies on the energy metabolism of bacteria.⁷⁶

The most common method of measuring the growth of bacteria in culture is by periodic counting of the number of cells present. This may be a viable count, made by quantititative dilution and plate culture, or as total cells by direct cell count, or indirectly as turbidity translated into numbers with a previously prepared calibration curve. Or the total number of bacteria present may be measured as dry weight.

When all, or practically all, the cells are viable and multiplying by binary fission, the rate of growth is exponential. This potential rate of multiplication may be realized only up to a certain point. As numbers increase in the microcosm of the culture tube,

competition between individual organisms for food stuffs, oxygen, and the like, progressively reduces the opportunity for further growth until a saturating population density is reached.

If no increasingly effective retardation were operative, the potential increase would be expressed by the relation:

$$\frac{dY}{dt} = bY$$

where Y is equal to the number of individuals per unit volume, and b to the rate of growth, or generation time, of the microorganism. When there is a maximal possible cell density, K, this geometric rate of increase is only partially realized, the extent of the realization depending on how near the culture is to its maximum density at any given time. Or, mathematically:

$$\frac{dY}{dt} = bY \frac{K - Y}{K}$$

This is the differential equation of the logistic function:

$$Y = \frac{K}{1 + e^{a - bx}}$$

This function, plotting as a symmetrical S-shaped curve, describes the growth of populations of a variety of living organisms. If the numbers of bacteria in a growing cul-

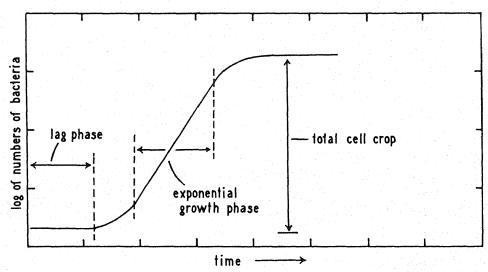

Figure 35. Diagrammatic representation of bacterial growth when the logarithms of the numbers of cells are plotted against incubation time.

ture are measured periodically and plotted against time of incubation, the points fall on a similar S-shaped curve, but one that is asymmetrical in that the point of inflection is not halfway between the upper and lower asymptote. Such curves are ordinarily plotted on semilog paper, i.e., the logarithms of the numbers of bacteria are plotted against time on an arithmetic scale. This procedure gives a more nearly symmetrical curve and has the advantage, not only of minimizing errors in counting, but also, when microorganisms are multiplying at an exponential rate. of the points falling on a straight line, and the generation time being expressed as the slope of the straight-line portion of the curve.

The bacterial growth curve, shown in schematic form in the accompanying figure, is divided into segments, or growth phases. The significant portions are the lag phase during which little or no increase in numbers occurs, the logarithmic or exponential growth rate phase during which the bacteria are multiplying at a maximum rate, and the stationary phase when the maximum total growth has been reached. The positive and negative growth acceleration phases at either end of the period of exponential growth are sometimes differentiated but are of limited utility. Following the stationary phase, death of some portion of the cells present usually occurs, rapidly or slowly and at an exponential rate; microbial death is considered elsewhere (Chap. Six).

It is obvious from even casual consideration of the development of the bacterial culture that descriptions such as "good growth" and "poor growth" have little meaning. Good growth may mean rapid growth and result from a relatively short latent or lag period and/or a short generation time during the exponential growth phase, or it may mean heavy growth in the sense that the maximal population density is high. These are not necessarily synonymous; the cholera vibrio, for example, grows equally rapidly in the logarithmic phase in aerated culture in peptone water, or peptone water enriched by the addition of serum to 10 per cent, but the maximal density is considerably greater in the enriched medium. The meaning of "growth" is, then, variable, and the growth response, however and to what purpose it may be defined, is a function of the environment in the microcosm of the culture vessel.

The lag phase. When bacteria are inoculated into fresh medium an appreciable time, or latent period, is required for adaptation to an environment new in the sense that it differs from that of the established parent culture. There is convincing evidence⁴⁰ that this period is divisible into an apparent and a true lag phase. The first is a consequence of the presence of cells in the inoculum which are not viable in the sense that they will not reproduce, although they may continue to metabolize, and thus reduce the size of the effective inoculum. Within limits, the length of the lag phase is directly related to the size of the effective inoculum, and the numbers of cells present during the subsequent exponential growth phase at successive points in time may be predicted from these considerations.

The true lag phase, in contrast, is the period required for the viable cells of the inoculum to accumulate enzymes, diffusible coenzymes, and essential intermediates in the synthesis of cell substance to the balanced concentrations consistent with synthesis at a maximum rate. When the inoculum is taken from a culture in the exponential growth phase, the lag is largely, or entirely, eliminated since the cells are already in a state of physiological balance making possible synthesis at a maximal rate.

On the other hand, the lag phase may be prolonged indefinitely bvinterference with processes of adaptation. Vigorous aeration, preventing the accumulation of small amounts of carbon dioxide from endogenous respiration that are essential to growth, prevents growth and multiplication. Similarly, the addition of antibacterial substances whose activity is primarily bacteriostatic, i.e., growth-inhibiting rather than killing, results in an indefinite extension of the lag phase. Such substances include those of practical importance as chemotherapeutic agents, such as the sulfonamides and certain of the antibiotics, as well as other substances such as certain dyes. These act by interfering with essential metabolic reactions, such as the synthesis of enzymes (Chap. Six), and when their effect is neutralized, as by p-aminobenzoic acid when growth is inhibited by sulfonamides, growth proceeds. The effect of many chemotherapeutic drugs is, then, in a sense an indefinite prolongation of the lag phase of bacterial growth.

The exponential growth phase. The stage in the development of the bacterial culture during which the cells are replicating at a constant and geometric rate represents an approximate, limited, steady state in the relation between the bacteria and their environment. The steady state is approximate because the environment is continuously altered by the microorganisms, and limited in that it persists over only a portion of the life history of the culture.

The rate of growth is obviously determined by limiting factors. These may be intrinsic in the structure of physiological potentiality of the cell, as, for example, the rate of diffusion across the osmotic barrier of the cell. Or they may be extrinsic in that they may be environmental factors, such as the concentration of an essential nutrient, concentration of oxidizable substrate, and the rate of diffusion of oxygen into the culture.

Continuous flow culture. 48, 58, 59 Bacterial growth in the logarithmic phase may be partially maintained by rapid successive transplant from this growth phase, but much more precisely by cultivation of the bacteria in a continuous flow of fresh medium. A considerable number of devices for this purpose have been constructed of which the chemostat and bactogen have been the most widely used. The former is operated by differential air pressure to provide a continuous supply of fresh medium to a small growth chamber as the used medium exhausted. In the latter the medium is continuously pumped into and out of a large rotating flask in which the bacteria grow in large volumes of culture medium. Both are operated at flow rates held at some fixed value below that required to maintain growth at a maximal rate. The steady state so obtained has been subjected to detailed mathematical analysis. A variation on this theme has been used in which the flow of fresh medium is controlled by a photoelectric system to maintain the numbers (turbidity) of bacteria at a constant level.

Under such constant cultural conditions one factor in the environment, such as concentration of a nutrient substance, may be varied, while the others are held constant in excess so that rate-determining effects may be measured precisely. Further, the kinetics of formation of products of synthesis may be studied in relation to gen-

eration time which becomes an experimental parameter. Theoretically, such a culture could be maintained indefinitely, but in practice it is limited because of the instability of the directive mechanisms of synthesis, *i.e.*, mutations occur and alter the character of the microbial population. On the other hand, the factors affecting spontaneous mutation rates may be studied under constant defined environmental conditions.

Synchronous cell division. 14, 75 In the usual bacterial culture cell division occurs at random to give, because of the large number of discrete events, a continuous increase in numbers of cells. By subjecting the culture to alternate incubation and chilling temperatures, it is possible to force the majority of the cells to divide within a short time and thus synchronize cell division. Studies on pneumococcus and the mouse typhoid bacillus have shown that the entire population is more susceptible to genetic transformation in the first instance, and to conversion to the lysogenic state (see below) in the second. Results such as these suggest that actively dividing microorganisms are relatively more susceptible to alteration of directive genetic mechanisms than are those in a resting state.

Cessation of cell division. Termination of the exponential phase of growth is marked by a relatively rapid decrease in the rate of cell division. Cell division does not stop entirely in the stationary phase, but the cells begin to die and occasional division counteracts deaths so that the number of viable microorganisms remains relatively constant for a time. This period may be relatively short so that within a few hours a decline in numbers of viable cells assumes an exponential rate, or the numbers of viable organisms may fluctuate about some median value that is usually less than the maximum cell density.

The decreasing rate of cell division may be accounted for in many ways, and different factors are operative with different microorganisms, and with the same microorganism under different conditions. Depletion of essential food substances may be the limiting factor but is probably not important with most kinds of culture mediums. The metabolic rate may be reduced by a lessened availability of substrates for the respiratory processes; thus a carbohydrate substrate may be reduced in amount, or

the rate of diffusion of oxygen may be insufficient at high cell densities. One of the most important kinds of factors is the accumulation of end products of metabolism, such as alcohols and organic acids from carbohydrates, to toxic concentrations. For example, the total cell crop obtainable from liquid culture is markedly increased by inclusion of a readily available source of energy, such as glucose, and vigorous aeration. The stirring effect of aeration keeps the substrate concentrations including that of oxygen, more or less uniform throughout the medium and provides excess oxygen so that not only do the oxidations proceed more nearly to completion with reduced accumulation of organic acids and the like, but the energy yield is increased. Under conditions such as these, the limiting factor is glucose concentration, and a cycle of growth may often be started by the addition of more glucose and sufficient alkali to neutralize the small amounts of accumulated organic acids.77

While these energy-yielding reactions and their products are an essential element in that they affect growth, their effect on growth is more precisely defined as that of control of biosynthesis,^{28, 71} expressed as the induction of synthesis of new enzymes as in the early stages of growth, the inhibition of enzymatic activity, and the inhibition of enzyme synthesis. These matters are considered in detail elsewhere (Chap. Five).

Morphological variation. Both the morphology and physiological activity of bacteria differ in the different growth phases of the culture. As growth gets under way, the maximum size that a given cell reaches before fission increases somewhat, and a large portion of the bacteria in a culture at this stage of development are appreciably larger than at other times. The cells stain evenly, and there is no evidence of granular structure even in those bacteria in which metachromatic granules are most readily demonstrable.

The rate of respiration per cell increases, reaching a maximum at the end of the phase of accelerating growth rate, and declining as the culture goes into the logarithmic growth phase. This increased metabolic rate is more apparent than real for it is quantitatively related to cell size.

The cell size decreases also as the culture goes into the logarithmic phase of growth, although the individual cells remain

homogeneous and stain uniformly. By the time the stationary phase is reached, the bacterial cells are uniformly smaller, and in cultures of spore-forming bacteria, many are forming spores. When the viable count begins to decrease, the cells no longer stain uniformly, but begin to show granular structure, and involution forms appear. ¹⁶

This succession of morphological types, the large embryonic or young cells, the smaller, uniformly staining, mature forms of exponential growth, and the senescent degenerating forms appearing in older cultures, has been designated cytomorphosis and is considered by some to be analogous to a similar succession of cell types in higher forms.

THE REPLICATION OF VIRUSES 54, 80, 83, 85, 87

Since the viruses are obligate intracellular parasites, consisting essentially of little more than a directive mechanism, virus replication differs from bacterial multiplication in that it involves a specific deviation in host cell synthetic processes, and the finished product is not a complete physiological system. Virus synthesis can be studied against the base line of normal host cell metabolism in a number of ways, such as the persistence or alteration of metabolic reactions associated with the formation of of virus. Or, the relative proportions of original virus substance, host cell substance, and metabolic substrate present in the extracellular environment that make up the new virus substance may be determined.

The consequences of this parasitic relationship to the host cell are variable. In some instances virus proliferation results in destruction of the host cell, such as the lysis of the bacterial cell by bacteriophage, or the degenerative changes produced in host cells in tissue culture by many of the animal viruses. In other cases, the host cell is relatively unaffected in that it continues an apparently normal existence while supporting virus production, and in still others, viral infection produces hyperplasia. These effects on the host cells in naturally occurring infections are in large part the basis of the pathogenesis and pathology of virus diseases.

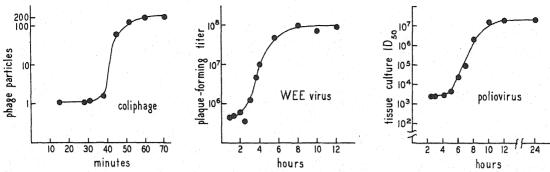

Figure 36. Growth curves of representative viruses. Coliphage and western equine encephalomyelitis virus are shown as one-step growth curves, the latter grown on chicken fibroblast culture and assayed by the plaque-counting method using a monolayer of chicken fibroblasts. The poliovirus type 3 was grown on HeLa cell culture and assayed by tissue culture ID₅₀. (Redrawn from Doermann, Dulbecco, and Ackermann and Francis respectively.)

Characteristics of virus replication. In general, a series of separable steps are involved in the proliferation of viruses. The first is an adsorption, more or less specific, of the infectious agent onto the surface of the host cell. Following adsorption, the particle penetrates the cell, and for an appreciable period, a few minutes to a few hours, cannot be detected as, for example, by breaking up the host cells and assaying the debris for virus activity. This is the latent, eclipse, or dark period during which the virus is said to be in the form of provirus. During this time the synthesis of virus substance is initiated, but active virus is not detectable until the infectious unit is organized through a process of maturation. Prior to this its presence is masked. Such an orderly sequence of events is inferred from the presence of "incomplete" virus in prematurely disrupted host cells, and its occurrence in mixture with complete virus under appropriate experimental conditions. There is no evidence suggesting that anything similar to binary fission of the intact virus particle occurs within the host cell.

In any case, when organization is complete, virus is liberated from the host cell at the end of the reproductive cycle, through breakdown of the cell structure or extrusion from the still functional cell. The liberation may be explosive, as with cell lysis, or virus may be liberated from the cell and shed into the environment over a period. Such a single cycle is called one-step growth. The free virus particles then invade other host cells and/or reinfect cells not destroyed in the previous process, and the cycle is repeated until the host cell substrate is ex-

hausted. In the infected host organism virus replication may be inhibited by the development of an effective immune response and combination of the free virus particles with antibody to interfere with repetition of the reproductive cycle.

In one-step virus growth breakdown of host cells is only partially synchronized in the first cycle, and subsequently becomes random, while continuous liberation of virus from infected host cells results in a continuous increase in virus. In either case, growth curves in which the amount, or titer, of virus is plotted against time are S-shaped and resemble the growth curves of bacterial cultures.

This general pattern of virus replication appears to hold for most of the viruses that have been sufficiently studied, with minor variations. Analogies may be drawn only with reservations, however, because it does not necessarily follow that similar stages in the development of widely different viruses are analogous.

THE REPLICATION OF BACTERIOPHAGE 15, 35

The bacterial viruses have been the most intensively studied of the viruses, largely for technical reasons, and are sometimes regarded as prototypes. While this may not hold true, the pattern of multiplication of these agents includes not only the stages observed with many other viruses, but also elaborations, some of which have not yet been observed with other viruses.

Adsorption.95 The adsorption of the virus particle onto the surface of the bac-

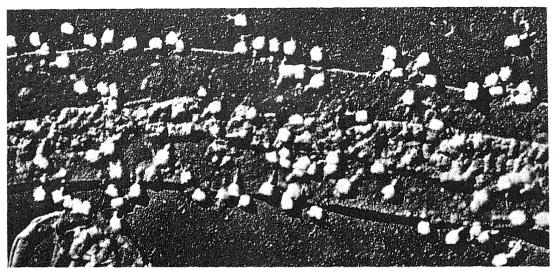

Figure 37. The interaction of T_2 coliphage with cell wall of E. coli B, showing the dissolution of the distal tail protein structure, in some cases leaving the protruding tail spike. The small rod-shaped particles may represent extruded spikes. \times 30,000. (Kellenberger.)

terial cell is highly specific and determines in large part whether or not the bacterium is "susceptible" to infection or, conversely, whether the phage is able to infect the strain or species of bacterium. At least in the Teven coliphages, the portion of the differentiated phage particle structure concerned in adsorption is the terminal portion of the tail, and the phage is adsorbed tail-first on the bacterium. Adsorption is inhibited in the presence of antibody to the distal tail protein which is presumably covered with a layer of immune globulin, but antibody is not effective after adsorption has occurred.

The initial reaction consists of establishing electrostatic bonds between the phage tail and the bacterial cell surface. There is reason to believe that the bonding occurs between amino and carboxyl groups, the

former predominating on the phage particle, and the latter on the bacterial cell wall.⁶⁹ There is some small but by no means complete correlation between the phage sensitivity of a bacterium and its somatic antigens. Phage does combine with purified polysaccharide-lipid somatic antigen, and with the lipocarbohydrate portion of the complex⁴⁹ of certain of the dysentery bacilli. The chemical substrate of the T-even coliphages is a similar substance, assaying 34 per cent lipid and 16.5 per cent reducing substances on hydrolysis, and located in a spherical body deeply embedded in the bacterial cell wall.⁹⁶

Infection of the bacterium.²⁷ For a short time the adsorption of the phage particle on the bacterial cell wall is reversible, but within a few minutes it becomes irreversible

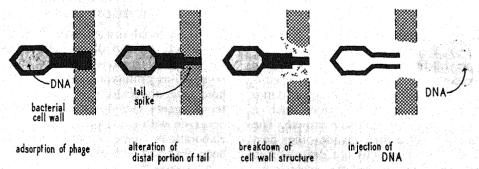

Figure 38. Diagrammatic representation of the sequence of events in the infection of the host cell by coliphage, proceeding from left to right. (Redrawn from Evans.)

when the distal tail protein breaks down, leaving the tail spike intact. As pointed out (Chap. Three), the structure of the distal portion of the tail appears to depend upon the integrity of thiol ester linkages, and there is sufficient zinc in the bacterial cell wall to catalyze the dissolution of the structure.

Following this, the structure of the cell wall breaks down locally with liberation of soluble nitrogen compounds, and the osmotic barrier is affected, allowing some leakage of cell contents. This appears to be associated with contact between the cell wall and the exposed tail structure, resulting in the activation of a heat-labile enzyme which depolymerizes the cell wall structure. Then the tail spike disappears, and the DNA content of the phage head structure is injected into the bacterial cell. The forces responsible for this are not known, but it is possibly relevant that, when the distal portion of the tail is removed by treatment with cadmium cyanide, emptying of DNA is accelerated in the presence of a variety of compounds, such as amino acids, amines, and amino sugars, having in common a positively charged amino nitrogen. On completion of this sequence of events, illustrated in schematic form in the accompanying figure, the attached phage particles may be broken off by treatment of the suspension in a blender. A short portion of the tail remains attached, and the remainder of the particle is an empty head and proximal tail membrane.

These events may also be produced in

vitro in the sense of apart from the intact living bacterial cell. Partial dissolution of the distal tail structure has been referred to above. In addition, phage particles may be adsorbed on purified cell wall preparations or reacted with purified lipocarbohydrate substrate as just described. Soluble nitrogen compounds are liberated in the first instance, and, in both, phage DNA is discharged into the medium with consequent inactivation of the phage.⁵³

Vegetative virus.⁵¹ The term vegetative virus has come to be used to designate proliferating intracellular virus in contrast to the resting stage status of extracellular, nonproliferating virus. The intracellular replication of bacteriophage occurs as a series of distinguishable morphological and biochemical events.

Very soon after infection there is a disruption of the chromatinic body structure, and these bodies are no longer demonstrable as discrete entities. No other overt changes occur until near the completion of the growth cycle when the cell substance has become obviously altered to a filamentous, net-like reticular structure from whose interstices the mature phage particles have escaped.

When the processes of replication are periodically interrupted in various ways, such as mechanical or chemical (cyanide) disruption of the infected cell or inhibition of phage replication by treatment with substances such as proflavine or 5-methyl tryptophan, and the material examined for activity and morphological elements, an orderly process is suggested. During the

Figure 39. The intracellular growth of T_2 coliphage in E, coli B; note that only the polyhedral head portions of incomplete phage are present. Second fixed in osmium tetraoxide. \times 60,000 (Kellenberger.)

early, or eclipse, portion of the latent period, neither phage activity nor distinctive morphological elements are demonstrable. Then spherical, empty bodies, containing little or no DNA, appear in increasing numbers, and these are regarded as phage particle precursors. By the middle of the latent period, mature infectious particles, complete with tails and DNA, may be found. These increase in number, presumably at the expense of the round particles since these decrease concurrently, until the full quota of infective particles, the so-called burst size, is reached, and the cell structure disintegrates to liberate them, leaving behind the reticulated structure described above. The mature phage particle, then, seems to be synthesized piecemeal and then assembled.

The only contribution made by the infecting particle to the new virus substance is a very small amount of DNA, less than 1 per cent of the total new viral DNA, and the remainder of the virus substance is synthesized by the host cell. Consistent with the morphological evidence, there is first an obligatory synthesis of viral protein very early in the latent period. DNA synthesis is occurring seven to eight minutes after the initiation of infection, with the

first mature phage particles appearing 12 to 15 minutes from the beginning of the infection, and continues until all the phage particles are mature and the bacterial cell lyses.

The phage protein is derived in only minor part, 15 to 30 per cent, from the bacterial protein, and is synthesized largely from the constituents of the culture medium. In contrast, practically all of the bacterial DNA is broken down into small fragments and reassembled as phage DNA. When this is insufficient in amount, phage DNA is synthesized from the culture medium. In addition, in the case of the T-even coliphages. the DNA constituent 5-hydroxymethyl cytosine, which does not occur in bacterial DNA, is also synthesized, from bacterial cytosine or from the culture medium. The synthesis of this component would seem to necessitate the formation of enzymes not normally present in the bacterial cell.

lysogeny.^{7,56} Two kinds of bacterial virus may be distinguished on the basis of their relation to the host bacterium. The one, virulent bacteriophage, produces the kind of infection of bacteria just described which culminates in lytic destruction of the host cell, and liberation of mature phage particles. The other kind, temperate bacteriophage, may give the production of

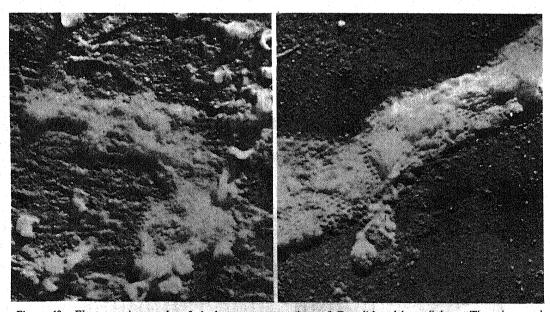

Figure 40. Electron micrographs of shadow-cast preparations of *E. coli* lysed by coliphage. The micrograph on the left shows the filamentous protoplasm; structure can be seen in the filaments just above the central mass, and the structure forms a net in the mass at the bottom. The separate opaque pieces casting long shadows are fragments of bacterial cell membrane. × 15,000. On the right the longitudinal filaments and interweaving cross-filaments are shown in an elongated bacillus undergoing lysis; note the oblique net in the lower left corner. × 22,500. (Wyckoff.)

LYSOGENY 91

active phage and its release by lysis, an abortive infection in which phage is not produced and disappears, or, finally a nonlytic infection in which active phage is not produced but persists in an inactive form indefinitely, i.e., becomes hereditary, in the bacterial host. Treatment of a susceptible strain of bacteria with a temperate phage usually gives some combination of these kinds of infection. A strain of bacteria infected in the last way is said to be lysogenic, and the phenomenon is called lysogeny. Lysogenicity tends to develop more frequently when there is multiple infection of the individual cell, i.e., when the phage is present in excess.

Lysogeny may be mimicked by a kind of carrier state in which virulent phage coexists with the phage-resistant bacteria, multiplying by infection and lysis of phagesensitive mutants occurring occasionally in the bacterial population. The two kinds of association may be differentiated by culture of the bacteria in a medium containing antiphage serum. In the carrier state, or mixed culture, the phage occurs free and is neutralized by antibody so that it is unable to infect the occasional sensitive cell and disappears in serial culture. In the lysogenic strain, the phage persists within the bacterial cells and is transmitted from mother to daughter cell during cell division and so is not affected by serial culture in antibodycontaining mediums.

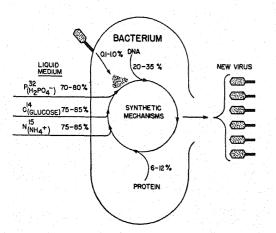

The classic example of lysogenic bacteria is the strain of coliform bacilli, coli-Lisbonne, isolated in 1922 by Lisbonne and

Carrere, which carries a Shiga dysentery bacillus phage. Many stock strains of bacteria are found, on examination, to be lysogenic, and possibly a majority carry phage.

The form in which the virus persists in the lysogenic bacterium is called provirus or prophage, but its nature is not clear. Like virulent phage in the eclipse stage of infection, it is not demonstrable in fragmented lysogenic bacteria, but there is reason to believe that the persistence of prophage represents more than an arrest of the normal processes of phage synthesis and replication. It is generally said that active phage is reduced to prophage, but it is not clear what is meant by reduction.

Virus may be shown to be present in the infected cells by treatment with ultraviolet light, x-ray and other ionizing radiations, nitrogen mustard (methyl bis-[β -chloroethyl]-amine), peroxides, etc. Many of the bacteria are killed since the required dosage is high, but in those which survive, the processes of phage synthesis and assembly are induced. The bacteria are lysed within a short time, perhaps two hours, with liberation of active phage.

The interrelationships between temperate phages and their host bacteria are relatively complex. In general, a lysogenic bacterium cannot be lysed by the active form of the phage it is carrying, and is said to be "immune," a state reminiscent of immunity to superinfection familiar in diseases such as syphilis.^{8, 97} Four others kinds of relationship are observed. First, there may be reciprocal cross-immunity between related

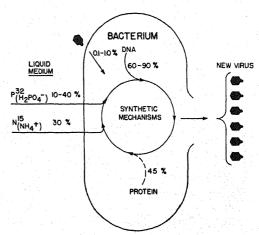

Figure 41. Diagrammatic representation of the source of phosphorus, carbon, and nitrogen in the synthesis of coliphage substance by the host cell. The percentages show the relative amounts contributed to the phage. Left, T-even coliphages; right, T_7 coliphage. (Evans.)

phage strains. Second, there may be a reciprocal sensitivity, i.e., the lysogenic bacterium carrying phage A may be superinfected with phage B, and vice versa. Third, there may be a partial dominance of one phage over another in that the lysogenic strain infected with phage A may be immune to phage B, but the lysogenic strain infected with phage B may be lysed by and/or superinfected with phage A. Finally, there may be complete dominance of one phage over another in that on superinfection the first phage is replaced by the second. In this last relation, the phage strains are said to be incompatible. Given the appropriate relation between phage strains, lysogeny may be multiple, and a lysogenic bacterial strain may carry several phages.

In bacteria infected with virulent phage, the entire directive mechanism of the host cell appears to be replaced by that of the virus, and the physiological system of the cell is literally under new management. In the lysogenic state the directive mechanism of the host cell is supplemented rather than replaced, and the host cell synthesizes provirus in addition to normal cell constituents.

The change may involve the synthesis of still other substances and, as well, minor modifications of the bacterial genetic apparatus. In consequence, characteristics of the bacterium, ordinarily regarded as inherent, biologically fundamental properties of the cell, may be attributable to, or modified by, the presence of phage in the lysogenic state.

These modifications are apparent in a number of ways. For example, the diphtheria bacillus is distinguished from the closely similar diphtheroid bacilli by its production of diphtheria toxin. Toxigenicity, however, has proved to be a characteristic only of lysogenic diphtheria bacilli, and may be removed by abolition of the lysogenic state or conferred on diphtheroid bacilli by making them lysogenic. Furthermore, characteristics of a lysogenic bacterium, either seemingly preexisting, such as biochemical characteristics or content of specific antigens, or acquired, such as drug resistance, may be transferred to another bacterium by making it lysogenic with phage derived from the first bacterium. This phenomenon of transduction, or infective heredity, is discussed elsewhere (Chap. Seven).

THE REPLICATION OF ANIMAL VIRUSES^{12, 61, 73}

Like the bacterial viruses, the animal viruses proliferate only on a living host cell substrate. Those suitable for this purpose are of two general kinds: the embryonated hen's egg and tissue cultures of animal cells such as epithelium and fibroblasts. Some kinds of cells may be maintained indefinitely in transplants like bacterial cultures, while others die off after a few transplants.

In either case, the growth substrate is actively metabolizing host cells which are induced to synthesize virus. The cycle of development is longer than that of the bacterial viruses; complete bacterial virus is formed as early as 20 minutes and seldom later than 90 minutes after the initiation of infection, while the growth cycle of animal viruses is a matter of hours, for example a minimum of four hours for influenza virus and seven hours for herpes simplex virus before the first complete virus is shed from the host cells.

While a living cell substrate is essential in the study of animal viruses, it is useful also in the study of pathogenic bacteria and host cell response. Meningitis may be produced in the chick embryo by the meningococcus; some of the early work with infectious agents in tissue culture concerned the growth of tubercle bacilli in macrophage cultures, and cultured tissue may produce antibody and show hypersensitivity reactions when the explants are taken from immunized animals.

Egg culture. (Chap. Two.) The cells present in the embryonated egg, not only those of the embryo proper but also those of the chorioallantois, the membrane lining the allantoic cavity, and so forth, are susceptible to infection with agents to which the chicken is resistant. This is an expression of the general phenomenon of increase in resistance, or natural immunity, coincident with tissue differentiation. A useful variation is removal of the embryo and culture of viruses in the remaining cells, such as those lining the allantoic cavity, in the de-embryonated egg.

Viral growth may be supported by one tissue but not another, or at one stage of differentiation but not another. For example, rickettsiae are cultivable to large numbers in the yolk sac of the six- to eight-day egg, equine encephalomyelitis virus in the tissues of seven- to nine-day embryos but in the yolk sac of the 15-day egg, influenza virus in the allantoic cavity of the 10- to 11-day egg, and vaccinia virus in the amnionic cavity of the eight- to nine-day egg when the rate of host cell multiplication is sufficient to replace those destroyed, and on the chorioallantois of the 12- to 14-day egg.

The pathology produced may simulate, to a greater or lesser degree, that of the infection in the natural host. The poxviruses, when cultured on the chorioallantoic membrane, produce pocks on the membrane with focal cell proliferation and subsequent necrosis and ulceration, and typical cytoplasmic inclusions. When the embryo is inoculated, tissues of endodermal and mesodermal origin are infected, and pock-like eruptions occur on the skin. Similarly, the virus of herpes simplex, when inoculated on the chorioallantois produces necrosis of ectodermal epithelium, and then infects mesodermal cells, and inclusions are found in endothelial cells. A herpetic encephalitis is produced in the embryo inoculated by the intracerebral route, and inoculation of the amnionic cavity results in vesicular lesions of the skin and mucous membranes of the pharynx in addition to a general infection of amnionic cells. On the other hand, cultivation of rickettsiae in the yolk sac, or influenza virus in the allantoic cavity, does not result in pathology similar to the natural infection or that induced in experimental animals.

Tissue culture. 82 Cultured cells for virus propagation may be primary explants, as in the case of monkey kidney cells, or established cell lines which may be carried indefinitely, like bacterial cultures, and are known by various designations such as L cells. HeLa cells, and KB cells. The cultures may be as monolayers on which some viruses produce grossly apparent discrete areas of cell pathology, known as plaques, and which are analogous to bacterial colonies. So-called spinner cultures, in which the cells are suspended, are useful also. The elements of basic cell culture techniques are described elsewhere (Chap. Two), and in considerable detail by others.70

Cytopathogenesis.²⁶ The proliferation of viruses is commonly, though not invari-

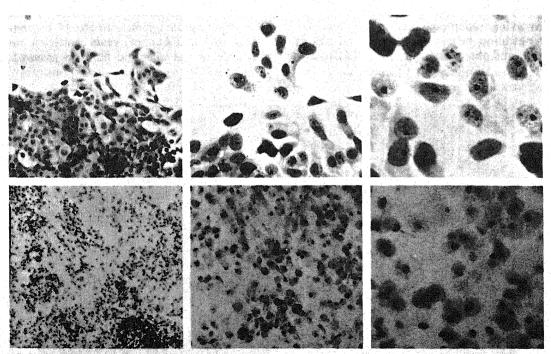

Figure 42. The cytopathology produced in HeLa cell culture of poliovirus type. I. Top row, uninfected tissue shown at magnifications of \times 65, \times 160, and \times 250, reading from left to right. ably, accompanied by changes in the host cells, the cytopathogenic effect of viruses. The kinds of visible changes produced allow the separation of viruses into groups, viz., those that produce only cellular degeneration, those that produce degeneration and also form inclusion bodies in the degenerated cells, and those that produce multinucleated cells or multinucleated syncytial masses of protoplasm together with degenerative changes with or without the formation of inclusions.

The first group includes agents such as the polioviruses, the Coxsackie viruses, foot-and-mouth disease virus, and Newcastle disease virus (NDV); the second includes poxviruses such as mouse pox (ectromelia) and vaccinia, fowl plague virus, and the viruses of the psittacosis-lymphogranuloma group; and the third group includes viruses such as those of herpes simplex and herpes zoster and varicella. A fourth group of viruses which grow in tissue culture without apparent visible changes in the host cells includes the viruses of influenza, St. Louis encephalitis, and yellow fever.

Developmental stages. The replication of animal viruses in egg or cell culture follows the general pattern described above. The initial absorption is specific, presumably involving receptor sites on the host cell. Penetration begins very soon after absorption, and the animal viruses differ from the

bacterial viruses in this respect, in that the process involves pinocytosis, with the cell playing an active role.^{21, 67}

While there may be some alteration of the virus particle on attachment, the viral nucleic acid is released from the nucleocapsid only after the particle has entered the cell. Following the eclipse period,⁵⁰ mature virus is released more or less continuously, and successive replication cycles may occur within the same cell, since the cell is not destroyed after a single cycle as in the replication of phage. In general, the entire process is much slower than that of bacterial virus replication, and usually takes several hours.

The animal viruses differ from one another in the details of the replication process; in some cases, for example, the mature virus particle is formed within the host cell, and in others assembly seems to be completed at the periphery of the cell and just prior to release. Influenza virus, herpesvirus, poliovirus, and poxvirus are considered here for illustrative purposes.

Influenza virus.³⁷ Proliferation of influenza virus in the entodermal cells lining the allantoic cavity of the embryonated hen's egg occurs readily, and it is one of the best known among the animal viruses in this respect. Following inoculation into the allantoic cavity of a 10- to 11-day embryo, the number of virus particles detectable in the allantoic fluid decreases at

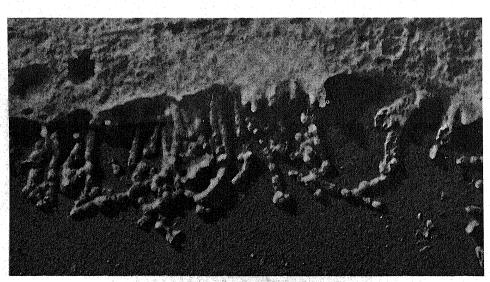

Figure 43. Shadow-cast ultrathin section of chorioallantoic membrane infected with influenza virus. The filaments extruded from the cells of the membrane appear to abstrict into spherical particles. × 10,000. (Wyckoff.)

an exponential rate, about 50 per cent disappearing in a little over an hour, as the virus is adsorbed to the host cells.45 During this early stage, infection of the cells may be prevented by RDE, i.e., neuraminidase, which destroys the red cell receptor functional in influenza virus hemagglutination (Chap. Three), and there is reason to believe that the host cell and red cell receptors are similar. Following adsorption, the virus particles enter the host cells, and the eclipse period lasts about four hours.

The first evidence of viral multiplication is the appearance in the middle of the eclipse period of soluble antigen, detectable by the complement-fixation test, which is not infective and has no hemagglutinin activity. In this connection it is of interest that, when the mature virus particle is disintegrated by shaking with ether, it breaks down to soluble complement-fixing antigen and hemagglutinin, suggesting that the soluble antigen may reflect an intermediate stage in virus synthesis.

Hemagglutinating activity, but not infectivity, is found in allantoic membrane extracts three to four hours after inoculation but does not increase in amount over that originally present in the inoculum until four hours and later. The hemagglutinating activity is not infective, and infective virus appears five to six hours after inoculation and is shed almost immediately into the allantoic fluid.23

Morphological studies of ultrathin sections of allantoic membrane by electron microscopy at this time show both spherical mature virus particles and filamentous structures, but no characteristic changes in the nuclei or cytoplasm of the host cell. The filaments appear to be formed by extrusion from the cell wall¹⁷ and are similar to those that may be produced by changes in osmotic balance. Both filaments and spheres appear to consist of a limiting membrane, a diffuse layer, and the spheres contain a dense central body about 20 m μ in diameter. The spheres seem to differentiate at or just beneath the cell surface, with assembly of the internal body, external layer, and limiting membrane.64

The relation between the filaments and spheres is not entirely clear. It is believed by some that they are separate structures, but others believe that the filaments are, or differentiate into, rows of spheres. The filament is broken down by treatment with acid, and the spheres are digested by trypsin after acid treatment.88

However this may be, the spherical forms, 60 to 70 mµ in diameter, represent the mature, hemagglutinating, infectious form of the virus. About 40 to 60 such particles are liberated in one growth cycle. The cycle is repeated by infection and reinfection of the cells lining the allantoic cavity, with the accumulation of virus in the allantoic fluid, until the system is exhausted after about 48 hours.

INCOMPLETE VIRUS.5, 57 Under appropriate circumstances incomplete, i.e., functionally deficient in that it is noninfectious, influenza virus may be produced. Deficient virus particles occur when the allantoic cavity of the embryonated egg is inoculated with very large amounts of virus, when the virus is grown in the allantoic cavity of deembryonated eggs, or when nonneurotropic (nonadapted) strains of the virus are grown in the mouse brain.

In the first instance, the inoculum must be sufficiently heavy, more than 1 hemagglutinating unit (HU) of virus, to give multiple infections of the allantoic cells; there are about 1×10^8 cells lining the allantoic cavity, and 1 HU of virus contains 1×10^6 to 1×10^7 virus particles. Presumably the virus-synthesizing capacity of the allantoic cell is limited, and when this limit is exceeded the cell responds by incomplete synthesis of a portion of the virus formed. In the second instance, removal of the embryo seems to affect the allantoic cells in such a way that they can support only partial synthesis of virus. In the third, virus has not been adapted to the host cell substrate present in the central nervous system in the sense that these cells are not fully competent to synthesize it.

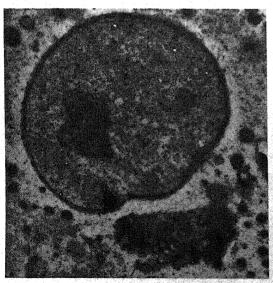

Incomplete or deficient virus differs from mature virus in that, while it agglutinates red blood cells and is specifically adsorbed to them, it is not only not infective and therefore unable to proliferate, but also it is smaller, with a sedimentation constant of 500 S as compared with one of 750 S for mature complete virus. A variety of considerations make it clear that incomplete virus is not a degradation product, but its appearance represents an arrest of the processes of synthesis and assembly of the mature virus particle.

Herpesvirus. 65, 78, 81, 93 Studies on the growth of other animal viruses have shown that the same general sequence of events, viz., adsorption, eclipse, and assembly and shedding of the virus, occurs with minor variations. Herpes simplex virus is of interest because of the formation of excess DNA within the nuclei of infected cells and the intranuclear formation of the virus. The virus is adsorbed rapidly on the chorioallantoic membrane of the embryonated egg. 50 to 80 per cent of the virus particles being adsorbed on the ectodermal cells in 15 minutes, and the adsorption is substantially complete in an hour. Adsorption is slower, e.g., 50 per cent in one hour, and two hours are required for complete adsorption in HeLa cell culture. 43, 94 The latent period is six to 12 hours, and virus increases exponentially for 10 to 20 hours thereafter, but excess DNA is demonstrable in the nuclei of infected cells as early as six hours after infection.89 The virus particles are demonstrable within the nuclei as nucleic acid enclosed in a single-layered protein coat. A second protein coat is acquired elsewhere. presumably in the cytoplasm, prior to shedding of the virus.

Poliovirus.^{22, 44} Poliovirus grown in monkey kidney and other cell cultures is completely adsorbed under optimal condi-

tions in two hours, and the eclipse period persists for three to four hours. New virus begins to accumulate intracellularly, and it has been reported that protein subunits. which appear in the cytoplasm, begin to aggregate as early as three hours after infection, leading to subsequent appearance of the typical icosahedral virus particle. There is evidence that protein and RNA³⁸ are synthesized independently, but not that RNA synthesis occurs in the nucleus. Recombination experiments have suggested that the protein aggregation about viral RNA tends to be indiscriminate, but in general the processes of synthesis of viral substance and maturation of the vegetative particle are poorly understood. Complete virus begins to be shed as early as five hours after infection, apparently relatively rapidly by the individual cell, but shedding is asynchronous and continues in the culture for 18 to 24 hours after infection.²⁴ The infected cells show marked morphological changes in nucleus and cytoplasm, tending to disintegrate as the virus is shed, and the cell is killed in a single cycle of virus replication.3

Poxviruses. 13, 55, 62, 79 Viruses of the pox group have been studied in some detail in this connection, and the observed morphological types of vegetative virus suggest an orderly sequence in the forms occurring

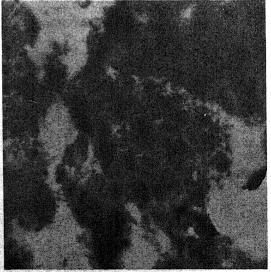

Figure 44. Electron micrographs of the developmental bodies of vaccinia virus. Left, early infection of a chorioallantoic cell of the embryonated egg, showing the nucleus of the cell and below it the matrix from which the virus particles originate. The developmental bodies in the matrix are few and appear to be "empty" membranes, and electron-dense mature virus particles are scattered in the cytoplasm. × 4000. Right, the differentiation of virus in an inclusion body in a rabbit corneal cell, showing the transformation of a part of the inclusion into virus particles, and developmental bodies of the virus in various stages of maturation. × 16,500. (Gaylord and Melnick.)

during the process of replication. Unlike influenza virus, which seems to be assembled in final form at or near the cell surface and shed almost immediately into the environment, at least some of the poxviruses are formed in masses of differentiated protoplasm well within the cell, and the cytoplasm of the host cell may be filled with mature virus particles in the later stages of infection. When the masses of differentiated protoplasm are dense, they constitute the typical inclusion body, and when they are less dense, i.e., inclusion bodies do not occur, the differentiated protoplasm constitutes a matrix from which the virus particles develop. This process has been studied in detail by Gaylord and Melnick²⁹ by electron microscopy of ultrathin sections of infected tissue embedded in methylacrylate, using vaccinia, ectromelia (mouse pox) and molluscum contagiosum viruses. These viruses are similar with respect to the morphology of both developmental and mature forms.

During active multiplication several kinds of particles may be seen. These include hollow spheres, spheres filled with material of low electron density, spherical-to-ovoid forms in which there is a small round, or larger bar- or dumbbell-shaped body of high electron density and finally ovoid bodies

of uniform high electron density that represent mature virus. Since the hollow spheres predominate early in the infection, and those containing electron-dense material predominate late in the infection, it may be inferred that the several morphological types of particles arise from one another in orderly sequence, the hollow spheres representing an early stage in the developmental cycle. The process appears to be the same whether the virus is formed in an inclusion body or in a matrix, though possibly less confined in the latter instance. For example, the same developmental forms of vaccinia virus are found in the cells of the chorioallantoic membrane of the embryonated hen's eggs where inclusion bodies are not common and in the rabbit corneal cell where they are produced regularly.

Infectious nucleic acid.^{20, 39} It is apparent from the nature of the replication cycle of bacterial viruses that the entry of viral nucleic acid into the host cell is the essential feature which determines the synthesis of virus by the host. A corresponding function of RNA of many animal viruses is directly demonstrated by the preparation of RNA from the virus as infectious nucleic acid which will similarly infect the host cell and induce it to form, not only the nucleic acid, but also the complete vegetative virus

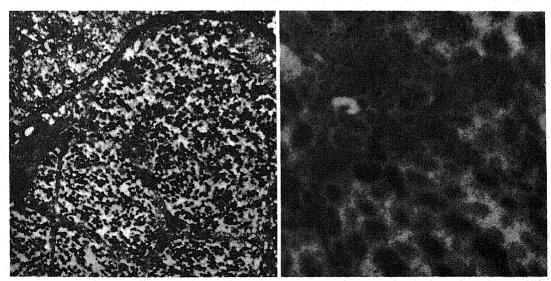

Figure 45. Electron micrographs of molluscum contagiosum virus in naturally infected cells. Left, a cell packed with mature virus particles separated into pockets by strands of cytoplasmic material. The nucleus is pushed to one side, and the nucleus is very dense. × 8000. Right, virus particles under high magnification, showing all the developmental stages from the virus precursors clustered in the remnant of cytoplasm to those having bar- or dumbbell-shaped masses of dense material in the center, and the mature uniformly dense particles × 26,000. (Gaylord and Melnick.)

particle. Extraction of RNA in 50 per cent phenol was described by Gierer and Schramm³⁰ for tobacco mosaic virus, and has subsequently been applied to a variety of RNA-containing animal viruses, for the most part small, neurotropic viruses, including poliovirus, the equine encephalomyelitis viruses, and certain of the arthropod-borne, ECHO, and Coxsackie viruses. The infectivity of such preparations is demonstrable by the inoculation of intact animals, the embryonated egg, and various kinds of tissue cultures, and is destroyed by treatment with ribonuclease. The yield of infectivity is low, commonly on the order of 0.1 per cent of the virus preparation from which the nucleic acid is extracted, but may be improved by use of hypertonic, on the order of 1 M., saline or sucrose solutions; such hypertonic solutions apparently both stabilize the nucleic acid infectivity and facilitate its entrance into the host cells.

Certain observations with soluble preparations of DNA derived from bacterial virus may be analogous. Solutions of the virus substance obtained by osmotic shock lysis and by extraction in concentrated urea infect host cell protoplasts which are not infected by intact virus. The activity is presumably that of DNA, especially in the urea-treated preparations, but the presence of functional protein is not completely excluded.

Host cells and tissues. 18, 31, 52, 72, 84, 91 As pointed out earlier, the synthesis of virus by a host cell represents a deviation of the normal processes of metabolism through the imposition of a new directive mechanism. The characterization of the processes of virus synthesis against the base line of normal host synthesis is one of both theoretical and practical significance. 34, 42

In general, virus proliferation appears to be an obligate aerobic process, occurring most actively, and usually exclusively, in the actively metabolizing host cell. There is little overt evidence of infection, viz., the endogenous respiration rate is not altered by infection. When the tissue is glucose-starved, virus production is enhanced by the addition of glucose and, to a lesser extent, pyruvate or alanine. Intact functioning of the citric acid cycle is apparently essential, and virus production is inhibited by substances such as fluoroacetate.

It is of considerable interest that the viral

infection may persist in host cell cultures which continue to multiply, resulting in a "carrier" state. 63 Walker 92 has distinguished four kinds of carrier culture: (a) those in which the majority of the host cells are genetically resistant and the virus infection persists in susceptible cells, which are in a minority: (b) those in which the host cells are susceptible to infection, but antiviral factors in the medium limit transfer of virus from cell to cell; (c) those in which the host cells are susceptible to viral infection, but interfering substances produced in the cell culture make the majority temporarily refractory; and (d) those in which the host cells are infected but not destroyed, the infection persisting through cell division. Such cell-virus relationships are not mutually exclusive, and more than one kind may occur simultaneously and/or a succession of such relationships may occur.

Cytotropism. There is a considerable degree of specificity between a virus and the kind of cell or tissue in which it is able to grow, i.e., which provides an appropriate substrate. It has already been noted in connection with virus culture in the embryonated egg that some viruses will grow in some tissues but not in others. The combination of tissue differentiation in higher animals and the obligate intracellular growth of viruses provides the basis for tissue predilection or cytotropism of viruses. This is not a unique feature of these agents for pathogenic bacteria may also show a similar affinity for certain tissues such as the preferential infection of the central nervous system by meningococcus, the predilection of typhoid and related bacilli for the bone marrow, and the relative noninfectivity of the cholera vibrio on parenteral inoculation, which is known as localization or elective localization rather than cytotropism.

Viruses are separable into a number of groups on this basis, that is, neurotropic, dermotropic, pneumotropic, and viscerotropic viruses. The neurotropic group includes agents such as the encephalitis viruses, which produce disease primarily of the central nervous system; the dermotropic group is exemplified by the poxviruses; the viscerotropic group is typified by yellow fever virus; and the pneumotropic group includes influenza, pneumonitis, and similar viruses.

Cytotropism is accentuated among the

viruses, fundamentally because of their complete dependence upon host cells for proliferation, and superficially because the symptoms of the diseases they produce derive in large part from the pathology of some kinds of tissues to the relative exclusion of others. It is, however, regarded as of less importance than formerly because it may be altered, and because virus-infected tissues may show no pathology and not contribute to disease symptoms. In the first instance, for example, naturally occurring viscerotropic yellow fever virus, dermotropic vaccinia virus, and pneumotropic influenza virus may be made neurotropic by passage in the mouse brain, etc. In the second place, it has become increasingly clear that the pathogenesis of at least some virus diseases involves multiplication in tissues other than those associated with the symptoms of the disease; poliovirus, for example, apparently multiplies in the tissues of the alimentary tract without histopathology and reaches the central nervous system by hematogenous spread.

Cytotropism remains a fundamental characteristic of viruses in that it is a consequence of the ability of the virus to multiply more readily in one kind of cell than in another, but it is a characteristic that is

subject to change.

MULTIPLE INFECTIONS AND INTERFERENCE

In view of the obligate intracellular multiplication of viruses, the interesting question of whether or not multiple infections may occur presents itself. While the undoubtedly complex interrelationships of viruses with one another and with the host cell are not yet fully understood, it is clear that multiple, often double infections may or may not occur, depending upon the viruses involved and upon the circumstances of infection.

Multiple infections. Two kinds of multiple infections may occur. The one, multiple infection of an animal, is spurious for present purposes when different cells and tissues are involved. The other kind of multiple infection is that in which the same host cell is infected simultaneously with more than one kind of virus, supporting independent growth of each, and at the same time continuing, to some degree, its own me-

tabolic activities. One such multiple infection, that of lysogenic bacteria with temperate bacterial viruses, has already been described. Among the other viruses, this may occur in some combinations of viruses, but not in others. One of the best examples is the simultaneous infection of the rabbit corneal cell with vaccinia and herpes simplex viruses in which the characteristic intranuclear herpetic inclusion and the cytoplasmic inclusion body of vaccinia may be found in the same cell. When the viruses are unrelated, such as these, the infections develop independently in that the viruses do not affect one another.

When a multiple infection with closely related viruses, such as the T-even coliphages or influenza virus variants, is produced by simultaneous exposure of the host cell, during the course of the mixed infection which occurs, there may be interaction between the two viruses, with recombination of characteristics and the appearance of

hybrid progeny (Chap. Seven).

Interference. 46, 90 Interference viruses occurs when a second infection cannot be superimposed upon an existing infection, or when one virus infects, i.e., multiplies, to the exclusion of a second. In the first instance it is necessary to establish infection with the first virus by prior inoculation, allowing a period at least half as long as that required for a single growth cycle to elapse before infecting with the second. For example, while mixed infections with T-even coliphages may be produced by simultaneous inoculation as indicated above, if infection of the bacterium with one phage is first established, the cell cannot be infected with the other phage, and the same holds true for influenza virus strains inoculated into the allantoic cavity of the embryonated egg. Similarly, mumps and influenza viruses are incompatible in that infection with one cannot be superimposed on an existing infection with the other.

In the second instance, when the interfering virus is inoculated in very large amounts it markedly inhibits growth of the other virus, resulting in either apparently complete protection or an abortive infection. For example, the intracerebral inoculation of nonadapted influenza virus in mice, incapable of more than a single multiplication cycle in this tissue, gives a high degree of protection against virulent western equine

encephalomyelitis virus by the same route for as long as a week, and normal susceptibility is not reached for three weeks. Similarly, under different experimental conditions, infection of rats with the same virus by the intranasal route is inhibited by St. Louis encephalitis or Japanese B encephalitis viruses given by the same route, with a reduction in mortality from 100 per cent to about 5 per cent. The latter kind of experiment illustrates the fact that interference is probably seldom fully effective, and some multiplication of the second virus may occur. It is not known whether this is due to a few host cells, which escaped the first inoculation, being infected by the second, or whether multiple infection occurs in some small number of cells.

Interference is not related to the initial adsorption stage of infection, nor is it produced by soluble components of viruses, but is apparently a consequence of the relation between the virus particle and the host cell after the synthetic mechanisms of the latter are affected.

Kinds of interference. The interference relationships between viruses are of two general kinds. The interference may be reciprocal in that either of a pair of viruses will prevent superinfection by the other. Or the interference may be effective in only one direction, i.e., one virus may be unable to superinfect, but the other can infect in the presence of an infection with the former. A third kind of relationship is, of course, that of noninterference resulting in the development of multiple infections of the kind described earlier. There appears to be little correlation between the kinds of interference effects, or lack of them, and other characteristics of the viruses concerned, and in this sense interference is nonspecific.

AUTO-INTERFERENCE. Attenuated or inactivated viruses may produce interference effects in heterologous systems, i.e., against diverse viruses, and they also inhibit multiplication of the corresponding homologous active virus. It was noted above that mixed infection of the allantoic cells of the embryonated egg may occur when the allantoic cavity is inoculated with variant strains of influenza virus. As in the case of the T-even coliphages, when infection with one strain is established, infection with the second does not occur. The "immunity" of lysogenic bacteria to lysis with the same

phage in active form is possibly analogous, with provirus interfering with active virus synthesis. Protection of the fox against infection with virulent distemper virus by the inoculation, either simultaneously or during the early incubation period, with large amounts of the ferret-adapted virus is a similar interference phenomenon.

When inactivated virus is used to interfere, the way in which it is inactivated is of some importance. Inactivation of influenza virus by treatment with formal-dehyde destroys the interfering property, inactivation by heat gives variable results, and inactivation by ultraviolet radiation gives uniformly effective interfering preparations. In the case of influenza virus, incomplete virus also interferes with subsequent infection with active complete virus.

MASKED VIRUS. Auto-interference also occurs when mixtures of inactive and active virus are used to produce infection, provided that the former is present in great excess, i.e., a thousand-fold or more, and in sufficiently high concentration. Mixtures of active and inactive virus may be produced by actual mixing, by partial inactivation, intentional or unintentional, or when incomplete virus is formed in relatively large amount. When such a mixture is inoculated in cell culture or susceptible animals, there is little or no evidence of the presence of active virus because of the interfering effect of inactive virus, and the viral activity is said to be masked.

Such a masking effect may occur when seed virus is stored for a long period or under conditions that cause the greater part of it to be inactivated. Similarly, this effect makes it difficult to titrate the end point of virus destruction with confidence, but in either case simple dilution of the inoculum may allow the demonstration of active virus if there is still sufficient present to allow the necessary dilution.

In animals infected with certain viruses, especially some tumor viruses, the activity may tend to disappear in serial animal passage by transplant of infected tissue, and the activity is said to be masked. It is possible that such masking may be due in part to the presence of inactive virus, but other factors, such as the concurrent presence of antibody, are significant also.

Nature of interference. It seems clear that viral interference needs to be considered as occurring at the cellular level. One

of the more attractive theories of interference is that of a competitive inhibition of incompatible viral nucleic acids, but this is not completely consistent with the interfering effect of inactivated virus.

Interferon.^{4, 11, 32} The resistance of cells to virus infection following pretreatment, or simultaneous inoculation, with inactivated or avirulent homologous or heterologous virus has been found to be attributable, at least in many instances, to the production by the host cell of substances known collectively as interferon. This phenomenon was first observed with myxoviruses, but it has been found subsequently that interferon production is stimulated by many viruses.

Interferon has been of very considerable interest in connection with its possible role in resistance to, and recovery from, viral infections. Functionally, its inhibitory activity is demonstrable as transfer of resistance from one cell culture to another in the absence of the initially interfering virus. It is quite specific with respect to species of host cells but has a relatively broad spectrum of antiviral activity, the arboviruses being the most resistant and the myxoviruses the most sensitive to it. It has been prepared in purified form, and appears to be a protein, is trypsin-sensitive, and has a molecular weight of 25,000 to 30,000.

It has no antiviral effect on extracellular virus, nor does it combine with viral nucleic acid, and apparently requires the mediation of the host cell. Pretreatment of cells with interferon does not result in immediate resistance to challenge infection, but an incubation period of several hours is required before maximal resistance is reached. It apparently stimulates the cells metabolically, in that aerobic glycolysis is increased concurrently with a decrease in phosphate uptake and utilization of glucose via the pentose shunt. Such evidence has been taken to imply that interferon itself may have no antiviral activity but rather serves to mediate such activity. In any case, it seems clear that the antiviral effect occurs in an early stage of virus replication, following uncoating of the virus particle, with prevention of the synthesis of viral nucleic acid.

The formation of interferon is a property of actively metabolizing cells, and that it is largely synthesized in response to an inducer is indicated by inhibition of its formation by actinomycin-D, an antibiotic which inhibits DNA-controlled RNA synthesis. While it appears to be largely newlyformed in virus infections, some may preexist as indicated by its appearance in the blood in response to endotoxin inoculation. It is probable that the capacity to produce interferon is inherent in the cells, but is ordinarily repressed in the absence of an inducer.

THE COMPARATIVE PHYSIOLOGY OF GROWTH

The physiological capabilities of microorganisms are an inverse reflection of their growth requirements in that the synthesis of cell substance from inorganic and simple organic compounds is a more complex process than that from more direct precursors of the constituents of protoplasm. Taken as a whole, microorganisms range in continuous series from the autotrophic forms capable of living in an inorganic environment, deriving energy from the oxidation of inorganic substrates or by a photosynthetic process. and assimilating nitrogen, carbon, etc., from inorganic sources, to the obligate intracellular parasites incapable of any, or at best rudimentary, independent physiological activity. The details of the processes of respiration, synthesis, and assimilation are considered elsewhere (Chap. Five).

In the strict sense of the term, only autotrophic microorganisms are not parasitic in that they are not dependent to some degree on other living organisms. Physiological limitations begin to appear in the heterotrophic forms, whose characteristic requirements of organic substrates for growth appear first as a requirement for organic carbon both as a source of energy derived by oxidation and as a source of intermediates for the synthesis of cell substance. Among the more fastidious kinds of microorganisms. the requirements for growth become more specific in that certain molecular structures. such as those represented in amino acids and fragments of enzymes or enzyme precursors, must be supplied preformed, but the microorganism is still physiologically independent in that it constitutes a complete physiological system.

Finally, the obligate intracellular parasites are set apart in that they are not complete physiological systems but are de-

encephalomyelitis virus by the same route for as long as a week, and normal susceptibility is not reached for three weeks. Similarly, under different experimental conditions, infection of rats with the same virus by the intranasal route is inhibited by St. Louis encephalitis or Japanese B encephalitis viruses given by the same route, with a reduction in mortality from 100 per cent to about 5 per cent. The latter kind of experiment illustrates the fact that interference is probably seldom fully effective, and some multiplication of the second virus may occur. It is not known whether this is due to a few host cells, which escaped the first inoculation, being infected by the second, or whether multiple infection occurs in some small number of cells.

Interference is not related to the initial adsorption stage of infection, nor is it produced by soluble components of viruses, but is apparently a consequence of the relation between the virus particle and the host cell after the synthetic mechanisms of the latter are affected.

Kinds of interference. The interference relationships between viruses are of two general kinds. THE COMPARATIVE PHYSIOLOGY OF GROWTH

The physiological capabilities of microorganisms are an inverse reflection of their growth requirements in that the synthesis of cell substance from inorganic and simple organic compounds is a more complex process than that from more direct precursors of the constituents of protoplasm. Taken as a whole, microorganisms range in continuous series from the autotrophic forms capable of living in an inorganic environment, deriving energy from the oxidation of inorganic substrates or by a photosynthetic process, and assimilating nitrogen, carbon, etc., from inorganic sources, to the obligate intracellular parasites incapable of any, or at best rudimentary, independent physiological activity. The details of the processes of respiration, synthesis, and assimilation are considered elsewhere (Chap. Five).

In the strict sense of the term, only autotrophic microorganisms are not parasitic in that they are not dependent to some degree on other living organisms. Physiological limitations begin to appear in the heterotrophic forms, whose characteristic requirements of organic substrates for growth appear first as a requirement for organic carbon both as a source of energy derived by oxidation and as a source of intermediates for the synthesis of cell substance. Among the more fastidious kinds of microorganisms, the requirements for growth become more specific in that certain molecular structures. such as those represented in amino acids and fragments of enzymes or enzyme precursors, must be supplied preformed, but the microorganism is still physiologically independent in that it constitutes a complete physiological system.

Finally, the obligate intracellular parasites are set apart in that they are not complete physiological systems but are de-

pendent upon the synthetic mechanisms of living host cells for their replication. It is more than coincidence that lack of independent metabolic activity is associated with the most minute forms, for there is literally not room within the small virus particle for the unknown but relatively large number of enzyme molecules required by a physiologically independent unit.

Since growth is the replication of the individual unit, and the replication is necessarily a directed process if individuality is maintained, microorganisms of diverse physiological capabilities may be equated on this common ground. The directive mechanism, or genetic control of synthesis, lies in pentose nucleic acid compounds, the deoxy form, or DNA, in bacteria and some viruses, and the RNA type in other viruses.

The mechanisms of the replication of DNA in situ by DNA polymerases and the direction of the processes of protein synthesis through the mediation of the various kinds of RNA and ribosomes (Chap. Three) have by now become clarified. In the bacteria the mechanisms of respiration and synthesis of the complete organism are present in each cell, but the viruses contain only the directive apparatus, conventionally enclosed in the capsid but active in the free state as infectious nucleic acid, and they parasitize the host cell with respect to high energy-yielding reactions and the synthetic functions of ribosomes (Chap. 3). Differences among microorganisms would appear. then, to be those of degree rather than kind.

The growth of microorganisms can be regarded primarily as an expression of pentose nucleic acid replication, complicated to a greater or lesser extent by the side reactions of synthesis of the remainder of the unit. Such a view not only places the multiplication of diverse microorganisms on a common ground, but also provides a basic working hypothesis for an interpretation of the ways in which the hereditary mechanisms of these forms may be altered (Chap. Seven). 83

Chapter Five

BACTERIAL METABOLISM

By JAMES W. MOULDER, Ph.D.

One of the fundamental principles of biology is that the chemical composition of all organisms is essentially the same and that their cell substance is synthesized by the same kind of chemical reactions; that is, the metabolism of all living things fits a single general pattern, a reflection of a common evolutionary origin. The complex edifice of cell structure is built from a relative handful of simple building stones needed for the life of all cells. These essential metabolites are synthesized by the same mechanisms and enter into the same reactions in organisms of diverse phylogenetic origin.

However, this concept of the unity of biochemical processes does not mean that the composition and metabolism of all cells is exactly the same. In fact, the difference between bacterial metabolism and the metabolism of higher organisms is the subject of much of this chapter. As already discussed, bacteria have many morphologic characters, such as the absence of a nuclear membrane, which show that they are primitive cells residing on branches near the base of the phylogenetic tree. Bacteria are also biochemically primitive, but in the sense of being unspecialized, not of being simple. It appears as if primordial bacteria often evolved a number of different ways of performing a specific metabolic task but that only one was selected for use in higher cells. However, these diverse metabolic mechanisms frequently persisted in bacterial evolution and may be found in present-day bacteria. For example, the only way animal cells can generate metabolic energy is by oxidizing one of a small number of different organic compounds. On the other hand, among present-day bacteria, there are those that can get metabolic energy from light, from oxidation of inorganic compounds, and from oxidation of a wide variety of organic compounds.

There is another fundamental difference between the metabolism of bacteria and the metabolism of higher plants and animals. As part of a multicellular organism, the plant or animal cell lives in a uniform internal environment and does not have to shift its metabolic patterns to adapt to sudden changes in its immediate surroundings. In contrast, the bacterial cell lives in the midst of an environment that changes frequently and violently. It copes with these changes by changing itself. A typical bacterium carries in its genome the information for making many more enzymes than it ever needs at any one time. In general, it will synthesize only those enzymes it needs for multiplying in a specific environment, and it will frequently cease this function as soon as an adequate amount of the products of this activity have been synthesized. Thus bacteria have a far greater metabolic flexibility than do higher cells, and under different cultural conditions a given bacterium may exhibit a diversity of metabolic pathways.

Respiration

In its broadest sense, bacterial respiration refers to all the energy-yielding reactions occurring within the cell. Except in photosynthetic organisms, these reactions consist of the oxidation of chemical substances present in the medium in which the bacteria are growing. Respiration has two main and often inseparable functions: (1) it furnishes the energy needed for the life and growth of bacteria and (2) it transforms a considerable portion of the compounds oxidized as energy sources into substances which are assimilated and synthesized into new cell material.

SOME BASIC CONCEPTS OF RESPIRATION

When one substance is oxidized, another must simultaneously be reduced. The oxidized substance loses electrons which are gained by the one reduced. This transfer of electrons is easily seen in the oxidation-reduction of inorganic ions. In the example given here, Fe⁺⁺⁺ clearly accepts an electron from Cu⁺ and is thus reduced to Fe⁺⁺.

$$Cu^+ + Fe^{+++} \rightleftharpoons Cu^{++} + Fe^{++}$$

When organic compounds are oxidized, as in most reactions of bacterial respiration, hydrogen atoms are transferred as well as electrons. Thus, malic acid transfers two hydrogen atoms and two electrons to pyruvic acid with the result that malic acid is oxidized and pyruvic acid is reduced, as shown in 1.

The majority of biological oxidations may be most simply considered in terms of hydrogen transfer, although it must be remembered that electrons are transferred in the oxidation of organic compounds, just as in the oxidation of inorganic ions.

Using the concept of hydrogen transfer, any biological oxidation may be considered to be a special case of this general reaction.

$$A-H_0+B \rightleftharpoons A + B-H_0$$

A-H₂ is the substance oxidized or the hydrogen donor, while B is the substance reduced or the hydrogen acceptor. One other component of the system is still needed. The oxidation-reductions of respiration do not proceed spontaneously, but require the presence of specific cell catalysts, the respiratory enzymes.

Biological oxidations are usually classified as either *aerobic* or *anaerobic*. If the hydrogen acceptor is molecular oxygen, *i.e.*,

$$A-H_2 + \frac{1}{2}O_2 \rightarrow A + H_2O$$

the oxidation is said to be aerobic. If a

O OH OH OH CH₃—CH₃—CH₂—COOH
$$\rightleftharpoons$$
 CH₃—CH—COOH \rightleftharpoons CH₂—COOH \rightleftharpoons CH₃—CH—COOH \rightleftharpoons CH₂—COOH \rightleftharpoons Dyruvic acid malic acid oxalacetic acid

substance other than oxygen serves as the hydrogen acceptor, the reaction is anaerobic. Anaerobic oxidation-reductions are often referred to as fermentations. Although the presence or absence of oxygen is of critical importance in the metabolism of many bacteria, the basic mechanisms of aerobic and anaerobic respiration are essentially the same.

Energy sources for bacteria. Bacteria make use of a far wider variety of energy sources than any other group of organisms. Photosynthetic bacteria utilize the energy of visible light, chemo-autotrophic organisms oxidize inorganic compounds as their sole source of energy, and heterotrophic bacteria oxidize almost every known type of organic compound. A few representative examples are listed in 2. In each case, the indicated reaction furnishes all the energy needed for growth of that species. The carbohydrates are the most widely utilized energy sources for heterotrophs, but acids such as succinic and lactic acids, the fatty acids, and the monohydroxy alcohols are also oxidized by many different bacteria. Most bacteria can use several different compounds as the main source of energy for metabolism and growth, some as many as a hundred. A few, however, have specific energy requirements. Thus, Clostridium kluyveri grows only when it can oxidize ethanol, while Nitrosomonas europaea must oxidize ammonia.

Mechanism of biological oxidation. Bacteria actually do not obtain energy from the substance oxidized in a single step, as suggested by the equations of table 2. These equations merely represent the overall process of biological oxidation and are the summation of many separate, consecutive oxidation-reductions, each catalyzed by specific respiratory enzymes. Consider the general equation for aerobic oxidation just written. In most bacteria, such a reaction involves at least the steps shown in 3 below.

Such a stepwise oxidation allows the cell to utilize the energy released in the oxidation in the most efficient manner possible and is characteristic of the reactions of intermediary metabolism in general. The chemical nature and detailed function of the respiratory enzymes involved will be considered later, but it should be noted here

- (1) Each respiratory enzyme exists in both an oxidized and a reduced state.
- (2) The respiratory enzymes enter into reversible oxidation-reduction reactions but are not used up in the overall process. They function catalytically as intermediate hydrogen carriers.
- (3) The enzyme that oxidizes the energy source (the *substrate*) cannot directly transfer the hydrogen and electrons of the substrate to oxygen, while the enzyme that finally does react with oxygen cannot oxidize the substrate. Therefore, the functioning of the complete chain of respiratory enzymes is essential for aerobic oxidation.

In most aerobic organisms this system is complete and functional, but in facultative and obligate anaerobes, portions of the hydrogen transport chain may be absent or nonfunctional (see below). In anaerobic respiration, the hydrogen and electrons of substrates are not transferred to molecular oxygen but to other substrates instead.

RESPIRATORY ENZYMES IN BACTERIA10

Dehydrogenases. 3 Dehydrogenases consist of a specific protein, or apoenzyme, combined with a reversibly oxidized and reduced coenzyme. They oxidize metabolites and are in turn reoxidized by other enzymes, not by molecular oxygen. Dehydrogenases possess a high degree of specificity for the substrate they oxidize

(1) A-H₂ + pyridinoprotein \rightleftharpoons A + pyridinoprotein-H₂ (2) pyridinoprotein-H₂ + flavoprotein \rightleftharpoons pyridinoprotein + flavoprotein-H₂ (3) flavoprotein-H₂ + 2 cytochrome Fe⁺⁺⁺ \rightleftharpoons flavoprotein + 2 cytochrome Fe⁺⁺⁺ + 2 H⁺ (4) 2 cytochrome Fe⁺⁺ + 2 cytochrome oxidase Fe⁺⁺⁺ \rightleftharpoons 2 cytochrome Fe⁺⁺⁺ + 2 cytochrome oxidase Fe⁺⁺ (5) 2 cytochrome oxidase Fe⁺⁺ + $\frac{1}{12}$ O₂ + 2 H⁺ \rightleftharpoons 2 cytochrome oxidase Fe⁺⁺⁺ + H₂O

^{3.}

and are usually named on the basis of their substrate specificity, *i.e.* lactic dehydrogenase, succinic dehydrogenase, etc. This substrate specificity is a function of the protein component, since a single coenzyme may be a part of several different dehydrogenases. The specific protein combines reversibly with both coenzyme and substrate, and the actual oxidation-reduction probably occurs while all three are in physical combination.

Two general types of dehydrogenases are found in bacteria and in other organisms. The *pyridinoproteins* are dehydrogenases containing either nicotinamide-adenine dinucleotide (NAD) or nicotinamide-adenine dinucleotide phosphate (NADP) as coenzymes. ¹⁶ The provisional structural formula of NAD is shown in 4. The structure of NADP is identical with that of NAD except for the presence of an additional molecule of phosphoric acid as shown in 4. Only the pyridine ring of both NAD and NADP undergoes reversible oxidation-reduction as indicated in the accompanying equation (5).

The pyridinoproteins are soluble, extracted from cells with relative ease, and their reduced forms are reoxidized by flavoproteins. In bacteria, the malic, lactic, and 3-phosphoglyceraldehyde dehydrogenases are NAD-proteins, while glutamic acid dehydrogenase is an NADP-protein. Many other bacterial dehydrogenases are also pyridinoproteins.

The cytochrome-linked dehydrogenases are associated with the insoluble particles of the cell. They were once thought to transfer the hydrogen of their substrates directly to the cytochrome system, hence their name. However, these enzymes are not single enzymes, but a complex of them. For example, succinic dehydrogenase, the most completely characterized complex of this nature, consists of at least the following components: (1) an iron-flavoprotein which oxidizes succinic acid to fumaric acid, (2) Slater's factor, (3) cytochrome c-linking factor, and (4) cytochrome b. These components react in a sequence, as yet not completely established, to transfer electrons from succinic acid to cytochrome c with the net result that succinic acid is oxidized and cytochrome c is reduced. Other microbial enzymes of a similar nature are the lactic dehydrogenase of yeast and the formic dehydrogenase of Escherichia coli.

Ferredoxin.³⁸ This is an iron-containing protein that functions as an electron carrier in anaerobic and photosynthetic bacteria. Depending on the species of origin, it contains four to seven molecules of nonheme iron per molecule of about 6000 molecular weight. Although it is a protein, it functions as a coenzyme of electron transport in a manner comparable to that of the pyridine nucleotides. The dark brown oxidized form of ferredoxin is oxidized to the reduced colorless state by appropriate enzyme systems such as the clostridial pyruvate dehydrogenase. It is reoxidized by other enzymes such as pyridine nucleotide reductase. Electron transport by ferredoxin plays a

nicotinamide-adenine dinucleotide (NAD)

* Position of third NADP phosphate group.

 $+2H^{+}+2e \rightleftharpoons N + H^{+}$

ribose-R

role in biological nitrogen fixation, bacterial photosynthesis, and numerous substrate oxidations by anaerobes.

Flavoproteins. 11 The flavoproteins are respiratory enzymes containing either riboflavin phosphate or flavin adenine dinucleotide as coenzymes (see 6).

In both riboflavin coenzymes, oxidationreduction is confined to the flavin portion of the molecule (see 7). Many flavoproteins contain one or more atoms of iron, molybdenum, or copper. The metals apparently facilitate the transfer of electrons from the reduced flavin coenzyme to the cytochrome system. Derivatives of riboflavin are present in all bacteria and are found in especially large amounts in some anaerobes. Some flavoproteins oxidize substrates with the formation of hydrogen peroxide (8). It is generally believed that such flavoprotein oxidases are usually responsible for the formation of hydrogen peroxide in bacteria. Other flavoproteins also oxidize substrates but transfer electrons to oxygen by way of the cytochrome system. Still others function in the chain of electron transport by oxidizing reduced pyridine nucleotides and then reducing cytochrome. These enzymes are called cytochrome reductases or dia-

flavin adenine dinucleotide

phorases. Flavoproteins of all three types are of apparently general occurrence in bacteria.

Oxygenases.¹³ Like dehydrogenases, oxygenases are oxidative enzymes that react directly with substrates. Unlike dehydrogenases, which catalyze the transfer of electrons and hydrogen from substrates to suitable acceptors, oxygenases catalyze the incorporation of molecular oxygen into substrates. These enzymes play an important role in the synthesis and degradation of amino acids, sugars, fats, B vitamins, and other essential metabolites.

Dioxygenases catalyze the incorporation of two atoms of oxygen into one molecule of substrate as in 9a. The enzyme that catalyzes this reaction, metapyrocatechase, has been crystallized from a member of the genus Pseudomonas. It contains one atom of Fe⁺⁺ per molecule. Pyrocatechase is also a dioxygenase from a pseudomonad, and it catalyzes a similar reaction (9b). However, it contains one molecule of Fe⁺⁺⁺ per molecule.

Monoxygenases transfer only one atom of oxygen to each substrate molecule, as in the oxidation of lysine by lysine oxygenase (10). This enzyme contains two moles of flavin adenine dinucleotide per molecule and no detectable heavy metals.

Iron-porphyrin protein enzymes.³⁶ Several important respiratory enzymes have ironporphyrin compounds as coenzymes. These iron-porphyrins are closely related to, but not identical with, the heme of hemoglobin. Only the iron atom of the iron-porphyrin undergoes reversible oxidation-reduction. Cells of higher organisms contain at least three iron-porphyrin protein pigments, the cytochromes a, b, and c, and other similar proteins. The cytochromes are usually, but not always, present in aerobic bacteria and absent in obligate anaerobes. Bacterial cytochromes differ from those of plant and animal tissues in absorption spectra, specificity, and other physical and chemical characteristics. Bacterial cytochromes are remarkable for their variety, both within a single species and among different species. The cytochromes take part in electron transport by accepting electrons from cytochrome reductase and passing them on to cytochrome oxidase.

Cytochrome oxidase, Warburg's respiratory enzyme, is a portion of the sub-

10.

$$\begin{array}{cccc} CH_2NH_2 & CHNH_2 \\ CH_2 & CH_2 \\ CH_2 & CH_2 \\ CH_2 & CH_2 \\ CHNH_2 & CH_2 \\ CHNH_2$$

microscopic particulate structure of the cell, but it may be brought into solution or stable suspension by treatment with ultrasonic vibrations. It is also an iron-porphyrin protein. Cytochrome oxidase is the enzyme which reduces molecular oxygen to H₂O to complete the last link in the chain of aerobic respiration. The identity and number of cytochromes functioning between flavoprotein and cytochrome oxidase is not known for most bacteria. More than one oxidase may be present in a single cell.

A few bacteria, such as *Streptococcus* fecalis and *Lactobacillus* delbrueckii, carry out aerobic oxidations in the complete absence of cytochromes or cytochrome oxidase. In these organisms, the respiratory enzyme that transfers electrons to molecular oxygen is a flavoprotein.

Most organisms contain an enzyme called *catalase* which decomposes hydrogen peroxide.

$$2H_2O_2 \rightarrow 2H_2O + O_2$$

The catalase crystallized from beef liver is an iron-porphyrin protein, and it has been generally accepted that catalase from other sources has a similar chemical nature, but recent evidence suggests that catalases other than iron-porphyrins may be present in some bacteria. Catalase is present in almost all aerobic bacteria and some facultative anaerobes, but under usual conditions of culture it cannot be detected in clostridia and some of the streptococci, lactic acid bacteria, and dysentery bacteria.

The *peroxidases* are enzymes, usually iron-porphyrin proteins but sometimes flavoproteins, which catalyze the oxidation of substrates by hydrogen peroxide. Their distribution in bacteria parallels that of the cytochromes and catalase, and their function in bacterial metabolism is uncertain.

THE RELATION OF BACTERIA TO MOLECULAR OXYGEN

The bacteria differ from one another in their relationship to molecular oxygen. Certain bacteria, the *obligate aerobes*, require ready access to air, growing feebly or not at all in its absence. Such organisms may lack certain respiratory enzymes necessary for anaerobic respiration, or the end products of their anaerobic metabolism may be toxic to them. The exact cause of their obligate oxygen requirement remains unknown. This group includes such well-known bacteria as the nitrifying bacteria, some of the sulfur bacteria, *Bacillus subtilis* and related forms, Azotobacter, the diphtheria bacillus, the cholera vibrio, and others.

However, most bacteria can grow in the complete or virtual absence of molecular oxygen. Two types of anaerobic bacteria may be distinguished. The most numerous are the facultative anaerobes, which respire with equal facility in the presence or absence of molecular oxygen. In broth cultures the dissolved oxygen is soon exhausted, and, after a preliminary period of aerobic growth, the culture continues to develop under essentially anaerobic conditions. The obligate anaerobes are unable to grow in the presence of molecular oxygen, and oxygen is actively toxic to them; vegetative cells die very quickly upon exposure to air, although spores are highly resistant. Members of the genus Clostridium, together with certain micro-aerophilic forms which tolerate very low concentrations of oxygen, are usually included in this group.

Bacteria are unexcelled in the possession of powerful and varied means for obtaining energy from nutrients in the absence of oxygen. The energy obtained from a given quantity of nutrients is usually much less under anaerobic conditions than in the presence of oxygen, because oxidation of substrates is less complete, and anaerobic metabolism is characterized by a rapid utilization of oxidizable substrates and a great accumulation of partially oxidized end products.

Bacteria perform energy-yielding oxidations anaerobically by using both inorganic and organic compounds as hydrogen acceptors instead of molecular oxygen. Thus, *E. coli* contains respiratory enzymes which couple the oxidation of lactic acid with the reduction of nitrate (see 11).

Bacteria also frequently couple oxidation of one organic compound with the reduction of a second. In this manner, glyceraldehyde may be oxidized by the enzymatic transfer of hydrogen to pyruvic acid (see 12).

This type of reaction is the chief mode of oxidation-reduction in the fermentation of carbohydrates, the chief anaerobic energy source for the great majority of bacteria. However, certain of the obligate anaerobes possess only a very limited ability to metabolize carbohydrate, and an important source of energy for these bacteria appears to be the coupled oxidation-reduction of pairs of amino acids.

CONSERVATION AND TRANSFER OF THE ENERGY RELEASED IN BIOLOGICAL OXIDATIONS^{17, 31}

So far nothing has been said of how energy released in respiration is conserved and made available for synthetic purposes. Yet these processes are as important as the energy-yielding reactions themselves, since energy simply liberated as heat (as in oxidation carried out in the test tube by the organic chemist) is not available for synthesis of new cell constituents.

The general principles involved are well illustrated by a reaction already discussed, the coupled oxidation-reduction of glyceraldehyde and pyruvic acid. Our present concepts of energy transfer in biological systems arose from detailed studies of this key reaction in carbohydrate fermentation (see below). Actually several different enzymes and coenzymes participate in this complicated reaction, but for the purposes at hand, it may be represented as shown in 13. Note that both inorganic and organic forms of orthophosphoric acid (H₃PO₄)

participate in the reaction. This is because the inorganic and organic phosphate compounds form an integral part of the energyconserving and transferring mechanism.

The key to the role of phosphate in energy metabolism lies in the difference between the two kinds of phosphate groups present in 1, 3-diphosphoglyceric acid. Let us see what this difference is and wherein lies its significance for biological oxidation.

1,3-diphosphoglyceric acid

Phosphate group A

 The phosphate group is united with the rest of the molecule through an ester linkage with a primary alcohol group.

(2) By analogy with simple and familiar organic compounds, this linkage may be compared with the ester bond joining ethanol and acetic acid in ethyl acetate.

(3) Like ethyl acetate, this *phosphate ester* is not easily hydrolyzed and liberates but little heat (energy) on hydrolysis.

(4) For these reasons, organic phosphate esters, as well as inorganic phosphate salts, are said to

12.

$$\begin{array}{ll} \text{CH}_2\text{OH-CHOH-CHO} + \text{CH}_3\text{-CO-COOH} + \text{H}_2\text{O} \rightleftharpoons \text{CH}_2\text{OH-CHOH-COOH} + \text{CH}_3\text{-CHOH-COOH} \\ \textit{glyceraldehyde} & \textit{pyruvic acid} & \textit{glyceric acid} & \textit{lactic acid} \end{array}$$

contain low-energy phosphate bonds, which are often designated by the shorthand notation, R-P.

Phosphate group B

(1) The phosphate group is united with the rest of the molecule through an anhydride linkage to a carboxyl group.

(2) By analogy, this bond may be compared to the anhydride bond between two molecules of acetic acid in acetic anhydride.

(3) Like acetic anhydride, this *phosphate anhydride* is readily hydrolyzed and liberates large amounts of heat (energy) on hydrolysis.

(4) Organic phosphate anhydrides are said to contain high-energy phosphate bonds, which are represented as R~P.

When the oxidation of 3-phosphoglyceraldehyde is coupled with the uptake of inorganic phosphate to form 1, 3-diphosphoglyceric acid, the energy liberated as heat is very much less than the heat released in the simple oxidation of glyceraldehyde to glyceric acid. The reason for this difference should now be apparent: the missing energy has been trapped and conserved in the form of the high-energy phosphate bond of 1, 3-diphosphoglyceric acid. The detailed reaction mechanism is shown in 14. All three steps are catalyzed by 3-phosphoglyceralde-

hyde dehydrogenase. 3-phosphoglyceraldehyde first combines with the thiol (SH) group of the enzyme to form a thiohemiacetal which is oxidized to a thioacyl group with NAD as the hydrogen acceptor. Finally in step (c), the thioacyl group is cleaved by the addition of inorganic phosphate to yield 1, 3-diphosphoglyceric acid and to regenerate the dehydrogenase in its SH form. Such a coupling of oxidation with the uptake of low-energy inorganic phosphate into highenergy organic phosphate compounds appears to be the chief method of energy conservation in all living cells. Therefore, representation of the general reaction of biological oxidation may be broadened to include the energy-conserving mechanism:

$$P + A - H_2 + B \rightleftharpoons A \sim P + B - H_2$$

(inorganic) (high energy)

There remains another problem—how the energy conserved in high-energy phosphate bonds is transferred to the appropriate place in the metabolic machinery where it may be used up in energy-requiring syntheses. Using the same example as before, this is what occurs:

1,3 diphosphoglyceric acid + adenosine diphosphate
 ⇒
 3-phosphoglyceric acid + adenosine triphosphate

 $Adenosine\ diphosphate\ (ADP)$

sine triphosphate (ATP) have the structure

shown in 15.

Note that ATP has two energy-rich bonds while ADP has only one, which is not usually active in energy transfer. This is the only difference between the two substances. All cells appear to have enzymes which reversibly convert one to the other by the addition or removal of an energy-rich bond. The resemblance of this reversible system to the reversibly oxidized and reduced hydrogen carriers is very striking. By analogy they may be called intermediate energy carriers or energy donors and energy acceptors, and this is exactly how they function in metabolism. ATP and ADP form the connecting

link between the energy-yielding reactions of respiration and the energy-demanding reactions of synthesis (see 16).

In subsequent sections, it will be seen that many types of oxidations, aerobic and anaerobic, inorganic and organic, generate ATP and that the energy stored in ATP is used in almost every type of biological synthesis. High-energy phosphate bonds are generated, not only during oxidations at the substrate level, but also in the oxidations accompanying the further steps in aerobic respiration. The steps in electron transfer implicated in oxidative phosphorylation are the reoxidation of NADH and reduced cytochrome.

Carbohydrate Metabolism

Carbohydrates serve a dual function in the metabolism of heterotrophic bacteria: (1) they are oxidized as the chief source of energy (ATP and reduced pyridine nucleotide) in most species and (2) they are the principal, and often the only, source of carbon for the synthesis of bacterial carbohydrates, lipids, amino acids, purine and pyrimidine bases, and all other organic cell constituents. In practice, these functions are inseparable. The metabolic transformations necessary for the assimilation of carbohydrates into cell material are often

also energy-yielding breakdowns. In addition, almost all the reactions involved in the degradation of carbohydrates are metabolically reversible and thus are also used for synthesis of new carbohydrates from small molecules such as CO₂, acetic acid, and ethanol.

Bacteria form a bewildering variety of products from carbohydrates, but their metabolism proceeds along a relatively few well-defined pathways of wide distribution in bacteria and in all other living things as well. Therefore variation in me-

tabolism among different species is not so much the result of fundamental differences in mode of metabolism as of differences in the relative importance of the several possible common pathways.

METABOLISM OF COMPLEX CARBOHYDRATES

Carbohydrates composed of two or more monosaccharide units linked together by glycosidic bonds are called complex sugars. Those with a definite small number of monosaccharide units are called oligosaccharides; most of them are disaccharides, such as maltose which is composed of two molecules of glucose. Polysaccharides contain a large and indefinite number of monosaccharide units. For example, the amylose fraction of starch contains molecules made up of straight chains of 300 to 1000 glucose units.

Hydrolysis of complex sugars.³⁵ Although free monosaccharides are widely distributed in nature, by far the greater bulk of naturally occurring carbohydrates are oligosaccharides and polysaccharides. With few exceptions bacteria must first break down the complex sugars into their constituent monosaccharides before they can be used as energy sources or as raw material for the synthesis of new protoplasm. This is done by cleaving the glycosidic bond uniting two monosaccharide units.

Bacteria break down complex sugars by three principal mechanisms, all of which may be illustrated with one sugar, sucrose. The examples in 17 give both the reaction and a typical enzyme which catalyzes it.

As will be seen in the section immediately following, the last two kinds of enzymes may also synthesize oligosaccharides and polysaccharides. However, hydrolysis of compound sugars is a virtually irreversible process and plays no important part in their synthesis. Nevertheless, bacteria possess a formidable battery of hydrolytic enzymes which are of great importance to the bacterium in utilizing the carbohydrate foodstuffs of its environment. They are of equal importance to the bacteriologist in classifying, identifying, and differentiating bacteria, because the presence or absence of enzymes hydrolyzing complex sugars largely determines the fermentation reactions of different species. Some of these enzymes are synthesized by the bacterial cell whether their substrate is present or not (constitutive enzymes), while others are produced only in the presence of the appropriate substrate (induced enzymes).

Relatively few species of bacteria are able to decompose *cellulose*, but those that do are widely distributed in the soil and the mud of sea bottoms as well as in the intestines of herbivorous animals. Cellulose is hydrolyzed to glucose, sometimes directly, and sometimes with the intermediate formation of the disaccharide cellobiose.

Unlike cellulose, *starch* may be hydrolyzed by a wide variety of living organisms, and the extracellular enzyme diastase, or amylase, is possessed by many bacteria.

(3) Transglycosidation

dextran

n sucrose $\xrightarrow{\text{dextran}}$ (anhydroglucose)_n + n fructose

sucrase $\xrightarrow{\text{dextran}}$

Like cellulose, however, starch is hydrolyzed in at least two stages, first to the disaccharide maltose, and second by a further hydrolysis to glucose.

Many disaccharides are also hydrolyzed by bacterial enzymes; sucrose by invertase, maltose by maltase, cellobiose by cellobiase,

lactose by β -galactosidase, etc.

Synthesis of complex sugars.¹⁵ The essential reaction in the synthesis of oligosaccharides and polysaccharides is the formation of the glycosidic bond. This reaction may be studied in its simplest form in the synthesis of disaccharides. Sucrose is formed from glucose-1-phosphate and fructose by the action of the enzyme sucrose phosphorylase found in *Pseudomonas saccharophila*, *Leuconostoc mesenteroides*, and other bacteria (see 17 [2]).

In contrast to the *hydrolysis* of sucrose by invertase, the *phosphorolysis* of sucrose by sucrose phosphorylase is reversible, and this enzyme readily synthesizes the disaccharide. This is because it is very hard to eliminate a molecule of water from the two monosaccharides in aqueous solution, while it is relatively easy to split out a molecule of phosphoric acid.

In syntheses catalyzed by enzymes of the

sucrose phosphorylase type, the problem of glycosidic bond synthesis becomes one of glucose-1-phosphate production. The formation of glucose-1-phosphate and its utilization for disaccharide synthesis is a good example of how the energy stored in ATP by oxidative reactions is used for synthetic purposes (18). Once glycosidic linkages are formed, other complex sugars may be formed by the transfer of monosaccharide units, or transglycosidation. Again, this mechanism may be illustrated with sucrose:

glucosido-fructoside + sorbose ⇒ (sucrose)

glucosido-sorboside + fructose

Note that the *number* of glycoside linkages remains the same. The glucose unit has merely been transferred from glycosidic linkage with fructose to glycosidic linkage with sorbose.

Other transglycosidases catalyze the formation of polysaccharides. Thus, the dextran sucrase of *Leuc. mesenteroides* forms from sucrose the polysaccharide dextran, which is composed of many glucose units (see 17 [3]).

Another type of transglycosidation in-

18.

glucose + ATP \rightarrow glucose-6-P + ADP glucose-6-P \rightleftharpoons glucose-1-P glucose-1-P + fructose \rightleftharpoons sucrose + H₃PO₄

Net reaction: glucose + fructose + ATP → sucrose + ADP + H₃PO₄

19.

uridine diphosphate glucose

volves the participation of a derivative of the pyrimidine uracil, uridine diphosphate glucose (19), as the monosaccharide unit donor. Yeast contains an enzyme which synthesizes sucrose according to the equation:

uridine diphosphate glucose + fructose ⇒ uridine diphosphate + glucosido-fructoside (sucrose)

Uridine diphosphate glucose is regenerated as follows:

uridine diphosphate + glucose-1-P→ uridine diphosphate glucose + P

If the examples discussed here are representative of the mechanisms responsible for complex sugar synthesis in all bacteria, it may be concluded that bacteria do not form oligosaccharides and polysaccharides by directly combining simple monosaccharides. Instead, they (1) from glucose-1phosphate or analogous compounds with the energy of ATP, (2) form initial glucosidic bonds by splitting out H₃PO₄ between glucose-1-phosphate and another monosaccharide or uridine diphosphate, and (3) form other disaccharides and polysaccharides by the transglycosidation reaction.

Great progress has been made in recent years in understanding how polysaccharides with more than one kind of monosaccharide unit are synthesized. For example let us consider the biosynthesis of hyaluronic acid, a polysaccharide occurring both in bacteria and in higher animals and of probable importance in certain bacterial infections. Hyaluronic acid is composed of a large number of basic units consisting of a molecule of glucuronic acid and one of Nacetylglucosamine (20). It is synthesized as shown in 21.

A number of important bacterial polysaccharides are synthesized by analogous mechanisms. 15 Among them are the polysaccharide moiety of murein, the structural polymer of the bacterial cell wall,27 the lipopolysaccharides of gram-negative bacteria, the teichoic acids of gram-positive bacteria, and the type-specific capsular polysaccharides of pneumococci.

BREAKDOWN OF HEXOSES AND PENTOSES

This topic is most simply presented by considering first the degradation of glucose. Since pentoses are frequent early products of glucose catabolism, the breakdown of pentoses is also discussed here. Finally, the way in which other common hexoses and hexose derivatives are channeled into the pathways of glucose metabolism will be shown.

(a) uridine diphosphate glucose + 2 NAD → uridine diphosphate glucuronic acid + 2 NADH

glucose-6-P → fructose-6-P fructose-6-P fructose-6-P + glutamine → glucosamine-6-P + glutamate glucosamine-6-P + acetyl-coenzyme A → N-acetyl-glucosamine-6-P + coenzyme A N-acetyl-glucosamine-6-P → N-acetyl-glucosamine-1-P

N-acetyl-glucosamine-1-P + uridine triphosphate -> uridine diphosphate-N-acetyl-glucosamine-1-P + P-P

(c) uridine diphosphate-N-acetyl-glucosamine-1-P + uridine diphosphate glucuronic acid → hyaluronic acid + 2 uridine diphosphate + P Diagram 22 outlines the four principal known pathways of glucose breakdown in bacteria. It should be used only as a guide to the detailed discussion of these pathways, for in order to show all possible modes of glucose degradation in a single diagram, certain simplifications have been made and alternate variations within a single pathway have been omitted.

All the mechanisms for breakdown of glucose may be roughly divided into three stages:

- (1) Conversion of glucose, by phosphorylation, oxidation, or by both processes, to a 6-carbon sugar which is the substrate for stage 2.
- (2) Cleavage of the carbon skeleton of the 6-carbon intermediate formed in stage 1 to two 3-carbon fragments or to a 5-carbon sugar (pentose) and CO₂.
- (3) Further metabolism of the reaction products of stage 2 to pyruvic acid (note exception in pathway 4).

The fate of pyruvic acid, the common product of all four pathways, will be the subject of the section immediately following.

Pathway 1: Nonphosphorylating oxidation of glucose. 14 Originally described in pseudomonads and acetic acid bacteria, these reactions have now been found in many other gram-negative and gram-positive bacteria.

The unique step in this mechanism is the direct oxidation, without prior phosphorylation, of glucose to gluconic acid. Further steps vary in different bacteria. An example of the pathway from glucose to pyruvic acid in *Ps. fluorescens* is shown in 23.

It is believed that considerable useful energy may be generated by means of phosphorylations coupled with the oxidation of glucose to 2-ketogluconate.

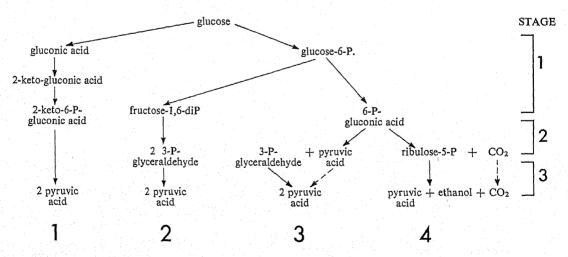

Pathways 2, 3, and 4: Formation of glucose-6-phosphate as a common initial step. Glucose is metabolized by way of the three remaining pathways by being first phosphorylated to glucose-6-phosphate by ATP and the enzyme hexokinase.

Pathway 2: Phosphorylating glycolysis.² Breakdown of glucose by phosphorylating glycolysis, the Embden-Meyerhof scheme, occurs in many bacteria, sometimes as the sole means of glucose breakdown, as in the homofermentative lactic acid bacteria, but more frequently in combination with other pathways.

The transformation of glucose to pyruvic acid by way of the Embden-Meyerhof scheme may be considered to proceed in four stages (summarized in 24).

(1) Formation of fructose-1,6-diphosphate. The hexose actually split to triose is fructose-1,6-diphosphate, formed as follows:

$$\begin{array}{c} \text{isomerase A} \\ \text{glucose-6-P} & \longrightarrow \\ \text{fructose-6-P} \end{array}$$

(2) Cleavage of fructose-1,6-diphosphate to triose. Fructose-1,6-diphosphate is split into two trioses, which are enzymatically interconvertible.

The occurrence of this aldolase reaction may be considered the unique reaction of the Embden-Meyerhof pathway.

(3) Oxidation of 3-phosphoglyceraldehyde. Of the two trioses formed in stage 2, only 3-phosphoglyceraldehyde is oxidized under normal conditions. The reaction is catalyzed by 3-phosphoglyceraldehyde dehydrogenase which contains NAD as a coenzyme. The detailed mechanism of this reaction has already been described.

The high-energy phosphate group of 1,3-diphosphoglyceric acid is transferred to ADP under the influence of another enzyme:

Finally, the reduced NAD is reoxidized by an appropriate hydrogen acceptor and its dehydrogenase. In the lactic fermentation, the reaction is:

$$pyruvic \ acid + \ NADH + \ H^{+} \ \frac{lactic}{dehydrogenase}$$

lactic acid + NAD+

In alcoholic fermentation, acetaldehyde is reduced to ethanol (see section on bacterial fermentations).

(4) Formation of pyruvic acid. 3-phosphoglyceric acid is rearranged to 2-phosphoglyceric acid:

Then 2-phosphoglyceric acid undergoes an intermolecular oxidation-reduction to phosphoenolpyruvic acid:

$$CH_{2}OH - C - COOH \xrightarrow{enolase}$$

$$CH_{2}OH - C - COOH \xrightarrow{enolase}$$

$$O \sim PO_{3}H_{2}$$

$$CH_{2} - COOH + H_{2}O$$

The formation of phosphoenolpyruvic acid is another example of how energy released in oxidations is conserved in high-energy phosphate bonds. Here the low-energy phosphate group of 2-phosphoglyceric acid is converted into the high-energy group of phosphoenolpyruvic acid.

In the final pyruvate-forming reaction, the high-energy bond of phosphopyruvate is enzymatically transferred to ADP.

phosphoenolpyruvic acid + ADP ⇒ pyruvic acid + ATP

Since many bacteria such as the homofermentative lactobacilli gain their energy from anaerobic oxidation of glucose to lactate, there must be a net production of energy in the process. A balance sheet in loss and gain of ATP makes this clear.

ATP used up per mole of glucose

- 1 ATP used for formation of glucose-6-phosphate from glucose
- 1 ATP used for formation of fructose-1,6-diphosphate from fructose-6-phosphate

Total 2 ATP used up

ATP formed per mole of glucose

- 2 ATP formed from oxidation of 3-phosphoglyceraldehyde to 3-phosphoglyceric acid (1 glucose → 2 glyceraldehyde)
- 2 ATP formed from transformation of 2-phosphoglyceric acid to phosphoenolpyruvic acid.

Total 4 ATP formed

Therefore, oxidation of one molecule of glucose to lactic acid results in the net formation of two moles of ATP.

Pathways 3 and 4: Formation of 6-phosphogluconic acid as a common step. Glucose-6-phosphate is oxidized to 6-phosphogluconic acid by dehydrogenases which in

most organisms require NADP as coenzyme (see 25).

Pathway 3: The Entner-Doudoroff pathway. 14 In many gram-negative bacteria, 6-phosphogluconic acid is cleaved to two 3-carbon compounds through the intermediate formation of 2-keto-3-deoxy-6-phosphogluconic acid. Thus, splitting of this compound identifies the Entner-Doudoroff pathway in the same way that the splitting of fructose-1,6-diphosphate identifies the Embden-Meyerhof scheme (see 26). The 3-phosphoglyceraldehyde may

then be converted to pyruvic acid by way of the reactions of pathway 2. The energy yield is one mole of ATP for each mole of glucose utilized.

Pathway 4: The pentose phosphate pathway. This pathway differs from the other three in that the carbon skeleton of glucose is split at two different places in two separate reactions. First, 6-phosphogluconic acid is cleaved into a molecule of CO₂ and one of pentose by 6-phosphogluconic acid dehydrogenase (see 27).

The next step is the cleavage of the pen-

ribose-5-P

xvlulose-5-P

ribulose-5-P

tose molecule by the enzyme transketolase as shown in 28. Its coenzyme diphosphothiamin (DPT) is firmly bound to the enzyme protein. The structure of DPT is given in 29, which also shows the structure of dihydroxyethyl-DPT, the active 2-carbon intermediate formed by reaction between pentose and transketolase.²³ DPT forms analogous compounds in several other important reactions soon to be discussed.

At this point, the metabolism of pentose diverges in two directions, depending on the fate of the dihydroxyethyl-DPT. One pathway is the formation of lactate, acetate and ATP (30). Subtracting the mole of ATP used to form glucose-6-phosphate gives a net yield of two moles of ATP per mole of glucose, the same as in phosphorylating glycolysis. The formation of acetyl-coenzyme A and acetylphosphate will be discussed in detail in a later section.

The other, more complicated pathway involves the conversion of three molecules of

pentose to one molecule of 3-phosphoglyceraldehyde and two molecules of hexose. The first step is the oxidation of three hexose molecules (C_6) to pentose (C_5) as shown in 27.

Second, two pentoses are cleaved by transketolase to dihydroxyethyl-DPT (C_2 -DPT) and 3-phosphoglyceraldehyde (C_3) as described in 28.

Third, in a reaction also catalyzed by transketolase, a molecule of dihydroxyethyl-DPT is transferred to the remaining pentose to form the 7-carbon sugar, sedoheptulose as shown in 31.

Fourth, the enzyme transaldolase splits the sedoheptulose into the tetrose, erythrose-4-phosphate, and an active 3-carbon intermediate (see 31), which is immediately condensed with a molecule of 3-phosphoglyceraldehyde to form fructose-6-phosphate (see 32).

Finally, the erythrose-4-phosphate and the remaining molecule of dihydroxyethyl-DPT

Relative importance of different pathways of glucose metabolism.⁷ Considerable efforts have been made to determine the relative importance of the different pathways of glucose breakdown in specific organisms. Of

various methods used to estimate the amount of glucose broken down by each pathway. perhaps the most successful has been the use of glucose labeled with the radioactive isotope of carbon, C14. A simple example will illustrate the method. If glucose labeled in carbon 1 with C14 is degraded by pathways 2, 3, and 4, pyruvic acid may be a common product. However, the pyruvic acid formed by Embden-Meyerhof glycolysis contains the isotope in the methyl group of one of each two molecules formed. The pyruvic acid produced by the Entner-Doudoroff route contains C14 in the carboxyl group of one molecule, and the pyruvic acid formed by way of the pentose phosphate pathway contains none at all, because all the C14 was released as CO₂. Although the situation is by no means simple, quantitative studies of isotope distribution in the end products of glucose breakdown allow a reasonably reliable estimate of the relative importance of the various pathways. Some representative results are given in the accompanying table. In organisms exhibiting more than one mode of degradation (probably the major class), the exact relative proportions are dependent on many environmental conditions.

Pathways of Glucose Breakdown

ORGANISM	PER CENT GLUCOSE DEGRADED BY		
	CLYCOLYSIS	PENTOSE PHOSPHATE PATHWAY	ENTNER-DOUDOROFF PATHWAY

BREAKDOWN OF PYRUVIC ACID

Bacteria dissimilate pyruvic acid by what appear to be many different mechanisms into the variety of end products which are characteristic of bacterial fermentations. There are common patterns in many apparently different modes of pyruvate breakdown which are probably of as regular and widespread occurrence as the Embden-Meyerhof glycolvsis.

Coenzymes of pyruvic acid metabolism. Three coenzymes are especially concerned in the metabolism of pyruvic acid: DPT, α -lipoic acid, and coenzyme A (CoA). Their constitution is indicated in the structural formulas in 29 and 35.

Diphosphothiamin¹⁶ is the coenzyme of the enzyme which catalyzes the decarboxylation of pyruvic acid to acetaldehyde. α-Hydroxyethyl-DPT is the primary product of pyruvate metabolism (see 36). It may be decomposed to yield free acetaldehyde or it may be further metabolized. Other α -keto acids, such as α -ketoglutaric

35.

α-Lipoic acid

pantothenic acid

Coenzyme A (CoA)

36.

acid, are usually decarboxylated by similar DPT-enzymes.

 α -Lipoic acid³² is a reversibly oxidized and reduced coenzyme which is the hydrogen acceptor in the oxidation of the acetaldehyde produced by decarboxylation of pyruvic acid (see 37). α -Lipoic acid is also a growth factor for both bacteria and protozoa.

Coenzyme A, ¹⁶ the acetylation coenzyme, is a complex structure composed of one molecule each of the growth factor pantothenic acid, adenylic acid, β -mercaptoethanolamine, and two molecules of phosphoric acid. It reacts with acetyl- α -lipoic acid to form acetyl-CoA (see 38). The reduced form of α -lipoic acid released in the reaction is reoxidized by an NAD-enzyme.

Reactions of pyruvic acid. (1) Reduction. In Embden-Meyerhof glycolysis, L(+)-lactic acid is formed from pyruvic acid by an NAD-specific lactic dehydrogenase. Other lactic dehydrogenases are found in organisms not containing the Embden-Meyerhof system. Leuc. mesenteroides has an NAD-dehydrogenase which forms the D(-) isomer of lactic acid from pyruvic acid. Some lactic dehydrogenases, such as that of L. delbrueckii, contain flavin nucleotides as coenzymes.

Pyruvic acid is also reduced to the amino

acid alanine in reactions of transamination (see below).

- (2) Nonoxidative decarboxylation and aldehyde transfer. These reactions have the same general mechanism and are catalyzed by DPT-containing enzymes. The first common step, the formation of α -hydroxyethyl-DPT, has already been described.
- (A) DIRECT DECARBOXYLATION. Yeast and many bacteria contain an enzyme, the classic pyruvic carboxylase of Neuberg, which directly decarboxylates pyruvic acid to free acetaldehyde and CO₂.

pyruvic acid + DPT-enzyme→
α-hydroxyethyl-DPT-enzyme + Co₂
α-hydroxyethyl-DPT-enzyme
acetaldehyde + DPT-enzyme→

The acetaldehyde may be reduced to ethanol, oxidized to acetic acid, or condensed with α -hydroxyethyl-DPT to form acetoin (see below).

(B) Transfer to acetalDeHyDE. Yeast, $E.\ coli$, and other organisms may transfer the α -hydroxyethyl group formed from pyruvic acid decarboxylation to a molecule of free acetaldehyde to form acetoin (see 39). Acetoin may be reduced to

- (C) Transfer to Pyruvic acid. Another molecule of pyruvic acid may also accept the α -hydroxyethyl group to form acetoin by way of α -acetolactic acid (40).
- (3) Oxidative decarboxylation. The first step in both oxidative and nonoxidative decarboxylation of pyruvic acid is the formation of an acetaldehyde-DPT-enzyme complex. In the oxidative process, this intermediate is then transformed to a highly reactive form of acetic acid, acetyl-coenzyme A.

acetaldehyde-DPT +

-lipoic acid \rightarrow acetyl- α -lipoic acid- H_2 + DPT

transacetylase acetyl-
$$\alpha$$
-lipoic acid- H_2 + CoA \Longrightarrow acetyl-CoA + α -lipoic acid- H_2

The energy made available by the oxidation of pyruvic acid to acetic acid is conserved in the form of acetyl- α -lipoic acid which, like acetyl-CoA, is a high-energy form of acetate.

The reduced lipoic acid is reoxidized by NAD (as already discussed). The NAD may then in turn be oxidized either aerobically or anaerobically.

Acetyl-CoA may also be formed from acetic acid. Two different modes of acetate activation are operative in bacteria.

acetyl-phosphate + ADP

$$\begin{array}{c} \text{acetyl-phosphate} + \text{CoA} & \xrightarrow{\text{phosphotransacetylase}} \\ & \text{acetyl-CoA} + \text{inorganic orthophosphate} \end{array}$$

In these reactions the energy of ATP is used to form an intermediate high-energy form of acetate which then reacts with CoA to form acetyl-CoA.

- (4) Reactions of acetyl-coenzyme A.
 (A) GENERATION OF HIGH-ENERGY PHOSPHATE BONDS. The energy of CoA formed by any mechanism can be used to generate ATP from ADP and inorganic phosphate by the reactions shown in 41.
- (B) DONATION OF ACETYL GROUPS. As important as the formation of high-energy phosphate is the role of acetyl-CoA as a form of "active acetate" used directly for synthetic purposes. This function is illustrated in the following two examples.

2 acetyl-CoA

The formation of acetoacetyl-CoA is probably the first step in the formation of long-chain fatty acids and of the various end products of the butyric acid fermentations (see below).

acetyl-CoA + oxalacetic acid → citric acid + CoA

This reaction is the first step in the complete oxidation of carbohydrates by way of the Krebs cycle (see below).

(C) FORMATION OF OTHER ACYL-COA COMPOUNDS. Coenzyme A serves a function in the metabolism of other metabolically important acids similar to that just described for acetic acid. Acetyl-CoA may react with these acids to form the corresponding acyl-CoA derivatives in reactions catalyzed by the enzyme CoA transphorase. For example,

acetyl-CoA + succinic acid ⇒
acetic acid + succinyl-CoA

The carbon skeletons of almost all cell constituents appear to be synthesized wholly or in part by addition of 2-carbon units to existing carbon chains by the acetylating action of acetyl-CoA. It is therefore apparent that the formation of acetyl-CoA represents a mechanism for the

conservation and transfer of metabolic energy as important as the formation of ATP.

The chief reactions of pyruvic acid in bacteria, a few of which are still to be discussed in later sections of the chapter, are summarized in 42.

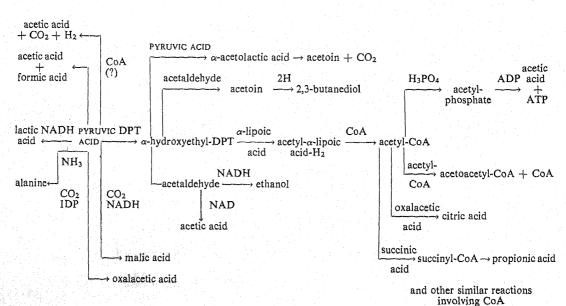

THE TRICARBOXYLIC ACID CYCLE^{21, 22, 24}

Aerobic bacteria can oxidize glucose completely to CO_2 and H_2O with molecular oxygen as the ultimate acceptor of electrons. Glucose and other carbohydrates are converted to pyruvic acid by the different mechanisms already described. The pyruvic acid is then completely oxidized by the concerted action of a series of oxidizing and decarboxylating enzymes operating as a cyclic process. This is the Krebs tricarboxylic acid cycle.

Pyruvic acid enters the cycle by being converted into acetyl-CoA, which in turn condenses with oxalacetic acid to form citric acid (see 43). The 6-carbon citric acid molecule is then decarboxylated and oxidized in a series of reactions to regenerate

42.

Metabolism of Pyruvic Acid in Bacteria

the 4-carbon oxalacetic acid molecule. Thus, the tricarboxylic and dicarboxylic acids of the cycle are not used up; *i.e.*, they act catalytically, but the pyruvic acid molecule is completely oxidized to CO₂ and H₂O. The reader can convince himself of this by summing up the oxygen used and the CO₂ and H₂O formed. (They are shown in boldface type in the diagram. Remember that H₂O is both formed and used up in the Krebs cycle.)

The enzymes involved in the Krebs cycle have been studied in great detail. The enzyme responsible for citric acid synthesis is known as citrate synthetase. Isocitric and malic dehydrogenases are NADP- and NAD-proteins, respectively. The α-ketoglutaric acid oxidase system is very similar to the pyruvic oxidase. Succinic dehydrogenase is a cytochrome-linked dehydrogenase. Oxalosuccinic decarboxylase catalyzes the reversible nonoxidative decarboxylation of oxalosuccinic acid. Two hydrases are also active in the cycle, aconitase and fumarase.

Anything capable of generating acetyl-CoA can be oxidized by way of the Krebs cycle—pyruvic acid, acetic acid, fatty acids, etc. In addition, α -ketoglutaric and oxalacetic acids are in metabolic equilibrium with the key amino acids, glutamic and aspartic acids, respectively. Thus, the Krebs cycle is of great importance, not only as a mechanism of terminal respiration, but also as a common meeting ground for carbohydrate, fat and protein metabolism (see below).

Utilization of the energy liberated in the tricarboxylic acid cycle. The most important product of the complete aerobic oxidation of carbohydrate is not CO₂ or H₂O, but energy. Approximately 10 times as much energy of potential metabolic use is liberated in the complete oxidation of glucose to CO₂ and H₂O as in the glycolysis to lactic acid. While there is a net synthesis of only 2 moles of ATP per mole of glucose converted to lactic acid, about 30 moles of ATP are formed for every mole of glucose oxidized by way of the Krebs cycle. The familiar observation that a facultative anaerobe (such as E. coli), given the same amount of energy source to oxidize, will grow to a much higher cell density aerobically than anaerobically indicates that bacteria derive much more

energy from aerobic oxidations than from fermentations.

The production of ATP via the tricarboxylic acid cycle is regulated by the concentrations of ATP, ADP, and adenosine monophosphate (AMP) in the intact bacterial cell:¹

$$\stackrel{\sim}{ATP} \stackrel{\sim}{=} \stackrel{\sim}{ADP} \stackrel{\sim}{=} \stackrel{AMP}{AMP}$$

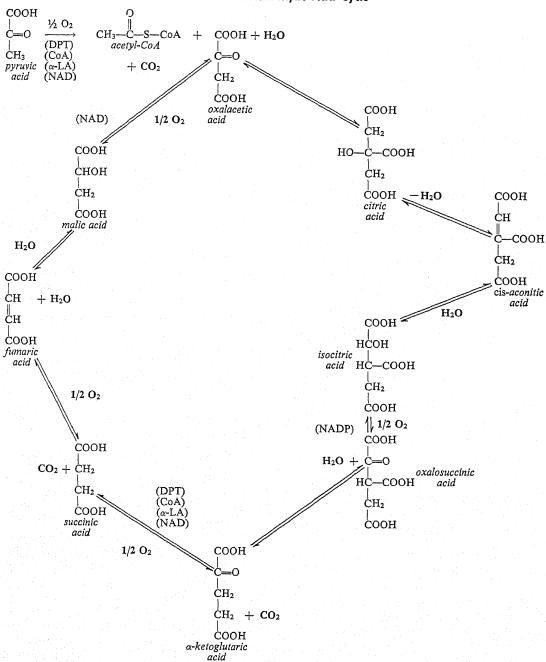

This regulation is achieved by action on three key enzymes, phosphofructokinase of the Embden-Meyerhof scheme (see 24) and citrate synthetase and isocitric dehydrogenase of the tricarboxylic acid cycle (see 43). AMP acts as a positive effector to combine with these enzymes at sites different from those binding their substrates (allosteric sites) in such a way that their rates of enzymatic activity are increased and thus also the rate of ATP synthesis. Since the concentration of AMP varies inversely with that of ATP, an increase in ATP concentration in the cell will reduce the rate of its synthesis, an example of negative feedback (or end product) control. There are probably also as vet undescribed mechanisms for regulating the flow of intermediates and reduced pyridine nucleotides through the tricarboxylic acid cycle and closely associated pathways.

The tricarboxylic acid cycle as a source of intermediates. The tricarboxylic acid cycle also serves an important synthetic function by providing carbon skeletons for the biosynthesis of many important cell constituents as, for example, α -ketoglutaric acid for the synthesis of glutamic acid. However, since each member of the cycle functions catalytically—one molecule is used up and one is formed for each turn of the cycle—this tapping of the tricarboxylic acid cycle for carbon skeletons will bring the operation of the cycle to an immediate halt if the acids withdrawn are not replaced.

Replacement occurs at the level of the 4-carbon dicarboxylic acids either by the fixation of carbon dioxide into 3-carbon acids (see below) or by a modification of the tricarboxylic acid cycle, the glyoxylic acid cycle (45). The two reactions of the glyoxylic acid cycle not shared with the conventional tricarboxylic acid cycle are catalyzed by the enzymes isocitratase and

43.

acid

malate synthetase (see 44). Diagram 45 shows that for each turn of this modified cycle, two acetic acid molecules are converted into one molecule of succinic acid.

Since the tricarboxylic acid cycle generates energy and no intermediates, while the glyoxylic, acid cycle generates intermediates but no energy, the bacterial cell must regulate the amount of acetyl-CoA fed into each cycle in order to meet changing metabolic demands. Regulation is achieved by control of both the activity and the synthesis of isocitratase. This enzyme is strongly inhibited by succinic acid, one of the products of its action. Thus, it is active when the succinic acid concentration is low and inactive when it is high. Most bacteria synthesize some isocitratase under all conditions, but its production is inhibited when succinic acid is added to the growth medium and

stimulated when acetic acid is the sole source of carbon. When acetic acid and other 2-carbon compounds are the sole sources of carbon, they must be assimilated by way of the glyoxylic acid cycle. Therefore, it must function at a high rate under these conditions.

FIXATION OF CARBON DIOXIDE

Almost all organisms possess, in widely varying degree, the ability to fix CO₂ into organic linkage. The general requirements for fixation are a source of energy and a source of electrons, because the reaction is an energy-requiring reduction. Living cells meet these requirements in many ways, but two main kinds of CO₂ fixation are

45.

The Glyoxylic Acid Cycle

Net reaction:

clearly distinguished: autotrophic fixation and heterotrophic fixation.

Autotrophic and heterotrophic ways of life. Introduction of these terms demands definition and explanation. All parasitic or saprophytic microorganisms derive their energy and most of their carbon from the oxidation of preformed organic compounds. In terms of the classification to be presented shortly, they are *chemoheterotrophs*. There is another large and widely distributed group of microorganisms of great biochemical interest and of critical importance in soil fertility and in the cycles of carbon, nitrogen, and sulfur in nature. These are the autotrophic bacteria. They obtain their energy from inorganic compounds or from light and their carbon from CO₂.

The word "autotrophic" means simply "self-nourishing." In the sense used here, this refers to the lack of any *organic* nutritional requirement. Autotrophic bacteria obviously have the same general nutritional needs as heterotrophs: sources of energy, carbon, nitrogen, and essential inorganic ions

It is appropriate at this point to inquire what is the essential difference between an autotroph and a heterotroph. Consider a representative of each metabolic type: the heterotroph E. coli grows in a medium containing only inorganic salts, ammonia, and an organic compound such as glucose; the autotroph Thiobacillus thiooxidans grows in a medium containing ammonia, elementary sulfur, and inorganic salts. The one absolute difference between the two is this: E. coli derives all of its energy from glucose oxidation and must have this oxidizable organic compound as an energy source in order to grow, while Thiobacillus thiooxidans oxidizes sulfur for its energy and is completely independent of any organic energy supply. The second difference between E. coli and Thiobacillus thiooxidans is that the autotroph uses CO₂ as its sole carbon source and from CO₂ synthesizes all the organic carbon of its cell. Now, while E. coli can also utilize CO₂, it is insufficient as a sole carbon source, and preformed organic carbon is also necessary for growth. Therefore, the second difference, the utilization of CO₂, is not absolute, but a matter of degree.

These differences in energy-yielding

mechanisms and in the extent to which CO₂ serves as a carbon source are probably the only differences between autotrophs and heterotrophs. In every other respect, the metabolism of autotrophic organisms appears to be just the same as that of heterotrophic organisms.

A useful classification of metabolic types of microorganisms based on energy and carbon requirements is as follows:

METABOLIC TYPE Autotroph	ENERGY SOURCE	ORGANIC CARBON REQUIRED	
chemo-autotroph	Inorganic com- pounds	No	
photo-autotroph	Light	No	
Heterotroph			
chemoheterotroph	Organic compounds	Yes	
photoheterotroph	Light	Yes	

All types except the photoheterotrophs will be discussed in this section. Note that not all photosynthetic bacteria are also autotrophic. One point to be remembered in using this classification is that a given organism may, under different conditions, show different types of metabolism. Taking two examples, Hydrogenomonas can live as a chemoautotroph by oxidizing hydrogen or as a chemoheterotroph by oxidizing organic compounds. It is said to be a facultative autotroph. Such behavior is common; there are only a few obligate autotrophs. Similarly, Rhodospirillum rubrum grows anaerobically in the light as a photoheterotroph and aerobically in the dark as a chemoheterotroph.

Autotrophic fixation of carbon dioxide.⁶ The cyclic mechanism whereby CO₂ is fixed into organic linkage by autotrophic organisms was discovered by Calvin and his associates in their studies on photosynthesis in unicellular green algae. However, the same cycle has also been shown to operate in the fixation of CO₂ by photoautotrophic and chemo-autotrophic bacteria. Therefore, the original designation of the cycle as "the photosynthetic carbon reduction cycle" may be broadened to "the autotrophic carbon reduction cycle."

Only two enzymes are unique to this cycle. The rest also function in other areas of carbohydrate metabolism. One of the new enzymes is *phosphoribulokinase*, which

catalyzes the reaction shown in 46. The other enzyme, carboxydismutase, catalyzes the actual fixation reaction in which CO₂ is fixed to ribulose-1,5-diphosphate with the formation of two molecules of 3-phosphoglyceric acid. The exact reaction mechanism is still in doubt, but it is usually formulated as in 47.

The remaining reactions of the autotrophic carbon reduction cycle are concerned with (1) the reduction of 3-phosphoglyceric acid to 3-phosphoglyceraldehyde and (2) the regeneration of ribulose-5-phosphate. The reactions of the cycle are given in detail

Reaction c through g also occur in Embden-Meyerhof glycolysis, while reactions h through m are also a portion of the pentose cycle.

The autotrophic carbon dioxide fixation cycle may be regarded as a modified pentose cycle in which occurs the unique reaction catalyzed by carboxydismutase. It has already been pointed out that CO2 fixation is an energy-requiring reduction. It is now apparent that the energy is supplied by ATP

Net reaction: $3 \text{ CO}_2 + 9 \text{ ATP} + 6\text{H}^+ + 6\text{(NADH or NADPH)} + 5 \text{ H}_2\text{O} \rightarrow 3\text{-P-glyceraldehyde} + 9 \text{ ADP} +$ 6(NAD+ or NADP+) + 8 H₃PO₄ and the reducing power by reduced pyridine nucleotide.

Carbon dioxide fixation by chemo-auto-trophic bacteria. These organisms generate the ATP and reduced pyridine nucleotide required for CO₂ fixation by oxidizing inorganic compounds. They can grow in the dark in the presence of only CO₂, inorganic nitrogen, and essential inorganic ions. Although chemo-autotrophs have no organic requirements, they usually have very specific requirements as to energy source. Many can live as autotrophs only by oxidizing a single inorganic substrate. The principal chemo-autotrophic bacteria and their energy-yielding reactions are given in the table below:

Carbon dioxide fixation by photo-autotrophic bacteria.³⁷ Green plants generate their ATP and reduced pyridine nucleotide for CO₂ fixation from the energy of light in reactions occurring in the chloroplasts.

(a) ADP + P
$$\xrightarrow{\text{light}}$$
 ATP

(b) ADP + P + NADP+ +
$$H_2O \xrightarrow{\text{light}} ATP + NADPH + H^+ + \frac{1}{2}O_2$$

Reaction a, termed cyclic photophosphorylation, also occurs in photosynthetic bacteria, but reaction b does not. In b, NADP is reduced by way of the photochemical cleavage of H_2O , a reaction peculiar to green plant photosynthesis. In

the photo-autotrophic green and purple bacteria, an oxidizable inorganic substrate is substituted for H_2O , and reduced pyridine nucleotide is generated enzymatically in the absence of a photochemical reaction. The most commonly employed substrate is H_2S .

Heterotrophic fixation of CO_2 . CO_2 may be fixed by heterotrophs in $C_1 + C_1$, $C_1 + C_2$, $C_1 + C_3$ additions, etc. Of these, the $C_1 + C_3$ reactions are probably of greatest quantitative importance and will be the only ones discussed here. For other important modes of CO_2 fixation, see 57.

Carboxylation of pyruvic acid to malic acid. The malic enzyme which catalyzes this reaction is widely distributed in bacteria.

pyruvic acid +
$$CO_2$$
 + $NADPH$ + $H^+ \longrightarrow malic$ acid + $NADP^+$

Carboxylation of pyruvic acid to oxalacetic acid. This reaction occurs in at least two different ways. Phosphoenolpyruvate is an intermediate in both. In one reaction, its phosphate group is transferred to a nucleotide diphosphate, and in the other it is released as inorganic phosphate.

(a) phosphoenolpyruvic acid + CO_2 + IDP (or GDP or ADP) \rightleftharpoons oxalacetic acid + ITP (or GTP or ATP) (b) phosphoenolpyruvic acid + $CO_2 \rightarrow$

oxalacetic acid + P

Carboxylation of propionic acid to succinic acid. This mode of CO₂ fixation is found chiefly in the propionic acid bacteria. It occurs as shown in 49.

The importance of CO₂ fixation. Organic carbon is constantly being converted into CO₂ by the respiratory activity of all living cells and by the breakdown of dead organic matter by saprophytic microorganisms. The CO₂ fixation of green plant photosynthesis is largely responsible for the return of this CO₂ to organic forms available to nonphotosynthetic organisms. Turning from the role of CO₂ in the economy of nature as a whole to its role in the economy of individual organisms, it is evident that, by definition, autotrophic organisms are completely dependent upon CO₂ as a carbon source. However, heterotrophic organisms cannot grow in the complete absence of CO₂, so CO₂ fixation must play a vital role in their metabolism as well. It is highly probable that at least one of the essential functions of CO₂ in heterotrophic economy is the replenishment of the 4-carbon members of the tricarboxylic acic cycle by means of the $C_1 + C_3$ additions just discussed.

BACTERIAL FERMENTATIONS⁴²

Bacteria anaerobically decompose, or *ferment*, carbohydrates to a relatively small number of 1-, 2-, 3-, and 4-carbon compounds. As indicated in 50, fermentation end products are usually produced by the breakdown of glucose to pyruvic acid. The pyruvic acid then reacts in various ways, all of which have already been discussed, to form the typical end product of fermentation (indicated by boldface type in 50). In a general way, fermentation end products may be regarded as the reduction products of fermentation with CO₂ as the oxidation product.

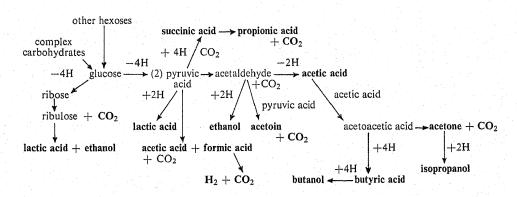

The chief metabolic value of the anaerobic breakdown of carbohydrate beyond the pyruvic acid stage lies in the extra energy

Bacterial Fermentation of Carbohydrates

made available, usually in the form of ATP. Bacterial fermentations are of practical importance because they produce products of industrial value (acetone, butanol, and so on) and because species differences in fermentation patterns are of great value in identifying and differentiating bacteria.

Most of the essential mechanisms involved in the metabolic transformations of bacterial fermentation have been considered in previous sections. The purpose of this section is to describe a few of the main types of fermentation patterns exhibited by important groups of bacteria.

Alcoholic fermentation. The oldest known type of fermentation is the production of ethanol from glucose.

Yeasts carry out an almost pure alcoholic fermentation, but although some alcohol is produced by many bacteria, it is the major end product in only a relatively few species.

Glucose is converted by way of the Embden-Meyerhof pathway to pyruvic acid, which is then decarboxylated to acetaldehyde by pyruvic carboxylase. The acetaldehyde is reduced to ethanol by alcohol dehydrogenase. NADH is the cofactor.

Lactic acid fermentation. In a typical lactic fermentation, pyruvic acid produced from glucose by way of the Embden-Meyerhof scheme is reduced by NADH formed in the oxidation of 3-phosphogly-ceraldehyde.

pyruvic acid + NADH + $H^+ \rightarrow$ lactic acid + NAD+

A very large number of bacteria form some

lactic acid, and it is the major fermentation end product of many (Lactobacillus, Streptococcus, Leuconostoc, Bacillus). If a given species, such as L. casei, produces only lactic acid from glucose by way of the Embden-Meyerhof pathway, it is said to possess a homolactic fermentation or to be a homofermenter. Others, such as Lactobacillus brevis, produce large quantities of lactic acid, but in addition form other end products such as acetic acid, ethanol, and CO2. They are called heterofermenters, and the fermentation is termed heterolactic (see below). A single species may show both types of lactic fermentation, depending upon such environmental factors as pH and substrate.

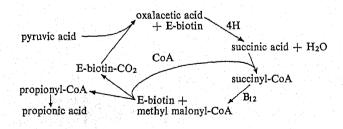

In heterolactic fermentations it was formerly assumed that the end products are formed by way of the Embden-Meyerhof scheme with pyruvic acid as an intermediate. However, this is not always true. As has already been seen in previous sections, glucose may be broken down by way of pentose or the Entner-Doudoroff pathway to typical heterofermentative end products such as CO₂, ethanol, lactic acid, and acetic acid without the participation of phosphorylating glycolysis.

Propionic acid fermentation. The propionic acid bacteria are closely related to the lactobacilli and get their name from their characteristic production of propionic acid from glucose. The propionic acid bacteria also form acetic and succinic acids and CO₂ as typical fermentation end products.

Propionic acid is formed from pyruvic acid by the cyclic process shown in 51. The cycle

51.

Formation of Propionic Acid

Net reaction: pyruvic acid + 4H → propionic acid + H₂O involves two novel reactions which merit attention (see 52).

First, CO₂ is transferred from methyl malonyl-CoA to pyruvic acid by a biotin-containing transcarboxylase without the formation of free CO₂. Biotin is also involved in other reactions of transcarboxylation.

Second, the conversion of succinyl-CoA to methyl malonyl-CoA requires the transformation of a straight-chain compound into a branched chain one. This is brought about by an isomerase containing a coenzyme form of vitamin B_{12} (methyl- B_{12}) (53). Similar "chain-straightening" reactions also occur in the metabolism of amino acids.

Fermentations of the coliform group of bacteria. Coliform bacteria ferment glucose to a variety of end products. E. coli produces lactic acid and ethanol by lactic and alcoholic fermentations. Lactic acid, acetic acid, and CO₂ are formed by the dismutation of two moles of pyruvic acid. By dismutation is meant the oxidation of one molecule and the reduction of the other. One molecule of pyruvic acid is oxidized to acetic acid and CO₂ as already described.

 $CO_2 + NADH + H^+$

The other is reduced to lactic acid by lactic dehydrogenase and the NADH produced in the oxidation of the first molecule of pyruvic acid.

pyruvic acid + NADH + H → lactic acid + NAD+

The net reaction is:

2 pyruvic acid → acetic acid + lactic acid + CO₂

Acetic and formic acids are also formed by a reaction restricted to the enteric bacteria, the *phosphoroclastic* reaction. The overall reaction is:

pyruvic acid + H₃PO₄ = acetyl-P + formic acid

This reaction is CoA and DPT dependent:

pyruvic acid + CoA
$$\Longrightarrow$$
 acetyl-CoA + formic acid acetyl-CoA + H₃PO₄ \Longrightarrow acetyl-P + CoA

ATP may be generated from acetylphosphate by reactions already described. If *E. coli* is grown in a medium with ammonium salts as the nitrogen source, formic acid is not further attacked, but if the medium contains certain amino acids, the enzyme *hydrogenlyase* is formed which breaks down formic acid to CO₂ and H₂.

The fermentation of glucose by Aerobacter aerogenes is similar to that of E. coli except that a considerable fraction of the fermented glucose is converted to acetoin. The production of acetoin is the basis for both the methyl red and the Voges-Proskauer tests for differentiation of E. coli from the aerogenes (cloaca) type of coliform bacilli. The Voges-Proskauer test is a color test for acetoin, while the formation of the neutral acetoin instead of acetic and formic acid makes the cloaca culture less acidic and thus methyl red-negative.

Butyl alcohol fermentations. Anaerobic organisms such as Cl. butylicum, Cl. aceto-butylicum, Cl. welchii, and Cl. kluyveri

52.

$$\begin{array}{c} transcarboxylase \\ methyl \ malonyl\text{-CoA} + E\text{-biotin} \xrightarrow{\hspace*{1cm}} propionyl\text{-CoA} + E\text{-biotin-CO}_2 \\ E\text{-biotin-CO}_2 + pyruvic \ acid \rightarrow oxalacetic \ acid + E\text{-biotin} \end{array}$$

COOH

$$CH_2$$
 EH_2
 EH_2

possess glucose fermentations characterized by the accumulation of butanol, butyric acid, and related products. The key reaction in the formation of such compounds is the CoA-catalyzed formation of acetoacetic acid. From acetoacetic acid are formed the end products typical of the butyl alcohol fermentation (see 54).

Lipid Metabolism

Bacteria contain a variety of lipids, the kind and amount frequently being highly dependent upon the exact conditions of culture. These lipids may be specifically incorporated into subcellular structures, such as cell walls and cytoplasmic membranes, or they may be stored as food reserves.

Hydrolysis of lipids.¹⁸ Neutral fats, which consist of a molecule of glycerol esterified with three fatty acid molecules, are hydrolyzed by lipases.

Phosphatides, or phospholipids, contain a molecule of glycerol, two molecules of fatty acid, a molecule of phosphoric acid, and a nitrogen base which may be choline, ethanolamine, or serine.

Choline-containing phosphatides are called *lecithins* (phosphatidylcholine). Those with ethanolamine and serine are called *cephalins* (more specifically, phosphatidylethanolamine and phosphatidylserine).

Lecithin may be used to illustrate the breakdown of phosphatides by bacteria (see 55). Phosphatidase A (lecithinase A) hydrolyzes off one fatty acid molecule to produce lysolecithin, a potent hemolytic agent. Lysolecithinase splits off another fatty acid to form glycerylphosphorylcholine. The same product is formed directly by the

54.

55.

Enzymic Hydrolysis of Lecithin

action of phosphatidase B. Phosphatidase D (lecithinase D) splits lecithin into a diglyceride and phosphorylcholine. This enzyme is identical with the α -toxin of Clostridium welchii.

Oxidation of fatty acids.¹² Fatty acids are oxidized by a mechanism closely similar to, but not identical with, the mitochondrial system for oxidation of fatty acids in higher animals. With butyric acid as an example, fatty acid oxidation proceeds in *Cl. kluyveri* as shown in 56. Reactions (2) through (5) are the same as in animal tissues, while reactions (1) and (6) are peculiar to bacteria.

Synthesis of fatty acids. 19 Bacteria synthesize saturated fatty acids with even

(1) $CH_3COSC_0A + ACP-SH =$

numbers of carbon atoms by the same pathway as do mammalian cells. The first step is the synthesis of malonyl-CoA from CO₂ and acetyl-CoA by the biotin-containing enzyme acetyl-CoA carboxylase (see 57). Compare these reactions with those in 49. In Cl. kluyveri and E. coli, further steps in fatty acid synthesis require a fatty acid synthetase which has 4'-phosphopantetheine (see 104 for structural formula) as its prosthetic group. This enzyme binds acyl groups as thioesters and has been called the acyl carrier protein (ACP). Six enzymes are required for converting acetyl-CoA and malonyl-CoA to butyric acid (58). Each enzyme requires ACP or the appropriate

acyl-ACP. The butyryl-ACP formed in reaction 58 (6) can be split to butyric acid or condensed with another molecule of malonyl-CoA to initiate another cycle of synthesis.

Saturated fatty acids can be oxidatively desaturated to unsaturated acids by enzymes requiring both molecular oxygen and NADP (59). Fatty acids containing cyclopropane rings are frequently found in bacterial lipids. They are synthesized by addition of a methylene group to the corresponding unsaturated fatty acid (60). The role of S-adenosylmethionine in reactions of 1-carbon transfer will be discussed later.

Synthesis of triglycerides and phospholipids. Triglycerides are probably syn-

the sized in bacteria by the esterification of glycerol with appropriate acyl-CoA compounds, but exact information is lacking at this time.

The phospholipids of *E. coli* are made as illustrated in **61**. The appropriate phosphatidic acid is synthesized from glycerol and acyl-CoA. It then reacts with cytidine triphosphate to form cytidine diphosphate diglyceride. The role of cytidine nucleotides in phospholipid synthesis is thus similar to the role of uridine nucleotides in polysaccharide synthesis. Serine is added to the cytidine diphosphate diglyceride to form *phosphatidylserine* which is decarboxylated to *phosphatidylethanolamine*.

Inorganic Nitrogen Metabolism 29

Nitrogen is an essential constituent of the last two great groups of metabolites to be considered, the amino acids and proteins and the nitrogen bases and nucleic acids. The metabolism of inorganic forms of nitrogen presents certain peculiar problems stemming mainly from the unusual unreactivity of molecular nitrogen as compared with that of other elements near it in the periodic table—carbon, oxygen, silicon, phosphorus, and sulfur. These elements occur in large quantities in the rocks of the earth's crust, but nitrogen-containing minerals are much rarer. Thus, the bulk of this vital element has remained as molecular nitrogen in the atmosphere.

Nitrate metabolism. Green plants, the ultimate food source of all nonphotosynthetic organisms, can generally use the nitrates found in all soils and natural waters

as their sole nitrogen sources. These nitrates are mainly obtained, not from nitrate deposits, which are very scarce, but from the breakdown of dead plant and animal matter in the soil.

Ammonia is produced in organic decompositions carried out by a wide variety of microorganisms. However, the oxidation of ammonia to nitrate can be accomplished by only a few specialized obligately aerobic, obligately autotrophic soil microorganisms of universal distribution. The first step is the work of bacteria of the genera Nitrosomonas and Nitrosococcus:

$$2 \text{ NH}_3 + 3 \text{ O}_2 \rightarrow 2 \text{ HNO}_2 + 2 \text{ H}_2\text{O}$$

The nitrite is further oxidized to nitrate by Nitrobacter:

$$2 \text{ HNO}_2 + O_2 \rightarrow 2 \text{ HNO}_3$$

Synthesis of Phosphatidylserine and Phosphatidylethanolamine in Escherichia coli

This process is called *nitrification* and the responsible organisms *nitrifying bacteria*.

Although few organisms can oxidize ammonia to nitrate, many higher plants, fungi, and bacteria can reduce nitrate to ammonia and thus can satisfy their inorganic nitrogen requirements with nitrate. Nitrate is reduced to nitrite by nitrate reductase and then to ammonia by nitrite reductase. These reductases are usually pyridine nucleotide-linked metalloflavoproteins. Ferredoxin may act as an electron carrier in the reduction of nitrite.

The nitrogen cycle in nature may then be represented in a most simplified manner by:

Some Agents of Nitrogen Fixation

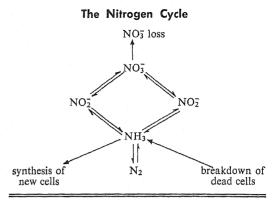

REPRESENTATIVE SPECIES	TYPE OF METABOLISM
Azotobacter chroococcum	Aerobic, heterotrophic
Clostridium pasteurianum	Anaerobic, heterotrophic
Nostoc (blue-green algae)	Aerobic, photosynthetic
Rhodospirillum rubrum	Anaerobic, photosynthetic
Rhizobium leguminosarum	Aerobic, heterotrophic; fixation occurs only in association with leguminous plants

However, the cycle is not perfect and nitrates are constantly lost to biological use. In terrestrial nitrogen cycles, nitrates are constantly leached away by soil water and eventually lost in the ocean. In addition, some soil bacteria, the *denitrifying bacteria*, reduce nitrate to molecular nitrogen.

Nitrogen fixation.³⁰ If there were unlimited amounts of soil nitrate, this constant loss would be of no importance. However, since this is not so, it is fortunate that a number of microorganisms can reduce molecular nitrogen to ammonia and thus make up the deficit. Nitrogen fixation is a widespread but sporadically occurring metabolic process. While comparatively few microorganisms have been positively identified as nitrogen fixers, the organisms known to be capable of reducing molecular nitrogen include a wide variety of metabolic types as seen in the accompanying table.

The first definitely identified product of the reduction of molecular nitrogen is ammonia. Some success has been achieved in understanding the mechanism of nitrogen fixation in one organism, the anaerobic nitrogen-fixer Cl. pasteurianum. Cell-free extracts from this bacterium loosely couple the oxidation of pyruvate with the reduction of molecular nitrogen to ammonia. Ferredoxin is the electron carrier that couples these two systems. About 100 moles of pyruvate must be oxidized to bring about the reduction of 1 mole of nitrogen. Since ferredoxin does not occur in aerobes such as Azotobacter, these nitrogen-fixers must

62.

use other mechanisms for reducing nitrogen to ammonia.

The previous nitrogen cycle may now be enlarged to include nitrate loss and its replacement by nitrogen fixation, as shown in 62

Primary uptake of ammonia into organic linkage. Since the nitrogen in most organic compounds of biological importance is at the state of oxidation of ammonia, it is not surprising that microorganisms generally introduce nitrogen into organic linkage in the form of ammonia.

Four main pathways for the primary uptake of ammonia are outlined in 63, together with examples of important nitrogen-containing metabolites synthesized by each pathway. The detailed mechanisms of these reactions will be given at appropriate places in succeeding sections.

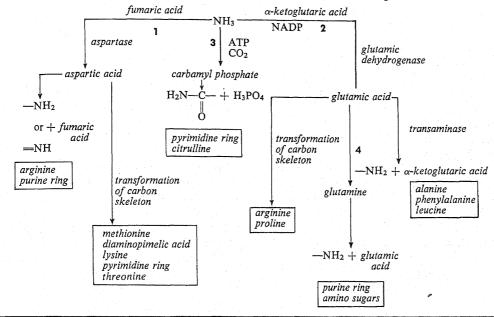

Metabolism of Amino Acids and Proteins²⁸

Amino acids occur in bacteria in the free state, in peptides, and in proteins. Most of them are found in proteins, but the small quantity of amino acids in the free state and in peptides is of great metabolic importance. Amino acids are not important energy sources for bacteria, except for the proteolytic anaerobes. Nevertheless, many bacteria degrade amino acids as well as incorporate them into protein. Both the degradative and synthetic phases of amino acid metabolism are closely integrated with the metabolism of carbohydrates, particularly through the reactions of the tricarboxylic acid-glyoxylic acid cycles.

BREAKDOWN OF PROTEINS35

Intact protein molecules do not readily pass into the bacteria cell and must be hydrolyzed to smaller units by extracellular enzymes before they can be utilized as nitrogen sources. Relatively few bacteria possess such extracellular proteolytic enzymes. Bacteria are usually separated into fermentative and proteolytic types according to whether carbohydrate oxidation or proteolysis characterizes their biochemical activities. Cl. sporogenes, Cl. histolyticum, Proteus vulgaris, and Ps. aeruginosa are examples of actively proteolytic bacteria.

Primary Uptake of Ammonia into Organic Linkage

Bacterial enzymes attack a wide variety of proteins and peptides.

BREAKDOWN OF AMINO ACIDS4

The ability to attack amino acids is much more widespread among bacteria than the ability to attack proteins. Bacteria may be divided into two groups on the basis of the variety of amino acids they are capable of breaking down. Gram-negative organisms such as E. coli, Pr. vulgaris, and Ps. aeruginosa attack almost all of the naturally occurring amino acids. Such organisms are also versatile synthesizers of amino acids and can grow on ammonia and a simple carbon source. In contrast, gram-positive organisms, such as the lactobacilli and the streptococci, have only a very limited ability to catabolize amino acids and also require a large number of amino acids as growth factors. Bacteria, particularly gram-positive species, can accumulate high intracellular concentrations of free amino acids, much higher than the extracellular concentration of the amino acids in the medium. This is accomplished by means of an energy requiring enzyme-like transport mechanism located at or near the cell surface.

Bacteria attack the amino acid molecule

in two main ways: decarboxylation or deamination. The enzymes catalyzing both types of catabolism are usually inducible, appearing only when their substrates are present in the medium.

Decarboxylation of amino acids. Bacteria carry out a nonoxidative decarboxylation of amino acids to the corresponding amines, as shown by the general equation:

$$R-CHNH_2-COOH \rightarrow R-CH_2NH_2+CO_2$$

Each decarboxylase is specific for a single amino acid, and the decarboxylation is complete and irreversible. Enzymes decarboxylating diaminopimelic acid, lysine, arginine, ornithine, histidine, tyrosine, phenylalanine, aspartic acid, and glutamic acid have been described.

With the possible exception of histidine decarboxylase, the amino acid decarboxylases have a common coenzyme, pyridoxal phosphate, which is a derivative of the growth factor pyridoxin or vitamin B₆.

pyridoxal phosphate

Pyridoxal phosphate is also a coenzyme for

other enzymes important in amino acid metabolism (see below).

Deamination of amino acids. Deamination of amino acids by the enteric bacteria. As a group, the enteric bacteria deaminate a large number of amino acids in several different ways.

OXIDATIVE DEAMINATION. Glutamic acid is broken down to ammonia and α -ketoglutaric acid by the glutamic acid dehydrogenase of $E.\ coli$ as shown in 64. This reaction is readily reversible, and glutamic acid can be synthesized from ammonia and α -ketoglutaric acid. Since glutamic acid can transfer its amino group to many other keto acids by transamination (see below), fixation of ammonia nitrogen in glutamic acid by glutamic dehydrogenase is of primary importance in the synthesis of amino acids in general.

Many enteric bacteria (but not E. coli)

contain amino acid oxidases which carry out the aerobic oxidative deamination of amino acids according to the general equation shown in 65. The amino acid oxidases are usually nonspecific with respect to substrate; the oxidase of *Pr. vulgaris* attacks 11 different amino acids.

Nonoxidative deamination. E. coli and related organisms contain enzymes catalyzing the deaminations shown in 66. The deamination of aspartic acid by aspartase is easily reversible and furnishes a second important pathway for the uptake of ammonia into amino acids, since aspartic acid, like glutamic acid, is very active in transamination reactions.

Tryptophan breakdown. E. coli attacks tryptophan only in its side chain and leaves the aromatic rings intact in the form of indole (cf. the degradation of tryptophan by pseudomonads). The reaction is shown in 67. Pyri-

64.

65.

R-CHNH₂-COOH +
$$\frac{1}{2}$$
 O₂ \rightarrow R-CO-COOH + NH₃ amino acid keto acid

66.

67.

doxal phosphate is the coenzyme for the reaction.

In contrast to the limited attack made upon tryptophan by E. coli, most Pseudomonas species attack both the aromatic rings and side chains of the amino acid.

Metabolism of amino acids by obligate anaerobes. The proteolytic species of the genus Clostridium do not ferment carbohydrate and must obtain metabolic energy from the oxidation of amino acids. Since they are obligate anaerobes, the ultimate hydrogen acceptor is not molecular oxygen but the amino acids themselves or their breakdown products.

The clostridia have evolved two methods for the anaerobic oxidation of amino acids. In one, the Stickland reaction, one amino acid is oxidized and one is reduced. In the second, amino acids are decomposed with the liberation of molecular hydrogen.

The Stickland reaction. Cl. sporogenes, Cl. botulinum, and other (but not all) species perform reactions of the general type shown in 68. Amino acid (1) accepts hydrogen atoms from (2) and is reduced to a fatty acid while (2) is oxidized to a keto acid. The equation indicates only the overall course of the reaction. It is likely that at least two enzymes, specific dehydrogenases for the reacting amino acids, and a hydrogencarrying coenzyme, perhaps one of the pyridine nucleotides, are required for a Stickland reaction. The coupled oxidationreduction of amino acids in these reactions proceeds at a rate comparable to the aerobic oxidation of carbohydrate in fermenters, and the Stickland reactions appear entirely capable of serving as the chief energy source for the proteolytic clostridia.

Decomposition of amino acids with liberation of hydrogen. Several clostridia which do not perform Stickland reactions decompose amino acids with liberation of NH₃,

CO₂, and H₂. The mechanism of such an "amino acid fermentation" is unknown.

SYNTHESIS OF AMINO ACIDS4

Heterotrophic bacteria synthesize amino acids from inorganic nitrogen, usually ammonia, and from simple organic carbon compounds such as acetic and pyruvic acids supplied in the medium or derived from the breakdown of other substances, usually carbohydrates. The great variation in structure among the 20-odd amino acids usually found in proteins means that amino acids are made by many different independent synthetic routes. However, several reactions or groups of reactions are of general importance in amino acid synthesis and will be considered before the biosynthesis of individual amino acids is discussed.

Uptake of ammonia. The primary uptake of ammonia into organic linkage has already been discussed (see Inorganic Nitrogen Metabolism). The ability to convert ammonia nitrogen into amino acid nitrogen is a common property of heterotrophic bacteria, and many heterotrophs can grow with ammonia as the sole source of nitrogen.

Mechanisms for the formation of glutamic and aspartic acids from ammonia and the corresponding keto acids have already been given. It is probable that a considerable fraction of the utilized ammonia is incorporated by way of glutamic acid and transamination reactions into many amino acids.

Transamination. Many amino acids undergo the general reaction of transamination (see 69). In transamination, the amino group of one amino acid is transferred to the α -position of an α -keto acid, thus synthesizing a new amino acid and a new keto acid. Transaminases are widely distributed in animals, higher plants, and bacteria.

68.

 R_1 —CHNH₂—COOH + R_2 —CHNH₂—COOH + $H_2O \rightarrow R_1$ —CH₂—COOH + R_2 —COOH + 2 NH₃

The transaminases are yet another group of amino acid enzymes for which pyridoxal phosphate is the coenzyme. Under appropriate conditions another member of the vitamin B₆ family, pyridoxamine phosphate, is also a coenzyme of transamination (see 70). Snell has suggested that these coenzymes function in transaminase systems as amino group carriers. Thus, the reaction between glutamic and oxalacetic acids proceeds as shown in 71.

Although many amino and keto acids participate in transamination reactions, glutamic and α -ketoglutaric acids have been a part of almost all transamination reactions so far described. These two acids may be thought of as an amino-group-carrying system, which may either accept amino groups from other amino acids or donate them to other keto acids. Transaminations are generally reversible reactions, and an amino acid which can donate its amino group to α -ketoglutaric acid can also be synthesized by the reverse reaction from glutamic acid and its keto acid analogue. In bacteria, transamination of the keto acids corresponding to glutamic acid, aspartic acid, alanine, serine, phenylalanine, tyrosine, leucine, isoleucine, and valine appears to be an important synthetic reaction. There are many different transaminases, each with definite substrate specificity.

Racemization and the importance of Damino acids. With the exception of glycine, each α -amino acid has an asymmetric carbon atom and therefore exists as two optical isomers, the D- and L- forms:

The amino acids of proteins are of the Lconfiguration, and it was once thought that only the L- form occurred in nature. The D- forms were often called "unnatural" amino acids, but they are also widely distributed in bacteria. D-Amino acids were first demonstrated in various polypeptides characteristic of the genus Bacillus: in the capsule of B. anthracis (D-glutamic acid) and in the antibiotics gramicidin and tyrocidine from B. brevis (D-leucine, D-valine, and D-phenylalanine). Penicillin contains D-valine and D-cycloserine is a derivative of D-serine. D-Alanine and D-glutamic acid are constituents of the murein component of the bacterial cell wall.

The amino acid racemases are enzymes that catalyze the racemization of optically active amino acids:

Pyridoxal phosphate is the coenzyme for these enzymes. Racemases for alanine, glutamic acid, threonine, methionine, proline, and diaminopimelic acid have been found in a number of bacteria, and it is clear that the ability to interconvert the optical isomers of many amino acids is a widely distributed bacterial property.

synthesis of amino acids derived from aspartic acid. The synthesis of aspartic acid by transamination or by the action of the enzyme aspartase has already been described. Once formed, aspartic acid may serve as the precursor of six other amino acids (see 72a). Of these, homoserine is an important biosynthetic intermediate but is not incorporated into cell structures, diaminopimelic acid is found only as a part of the cell wall muropeptides, and the other four are major constituents of bacterial proteins.

The key intermediate in the further metabolism of aspartic acid is aspartic β -semi-

aldehyde, which is made as shown in 72b. It is then converted into diaminopimelic acid and lysine (72c) or homoserine (72d), which in turn is the precursor of methionine (72d) or of threonine and isoleucine (72e).

The first step in diaminopimelic acid biosynthesis is the condensation of aspartic semialdehyde with pyruvate to yield, after dehydration and reduction, 2,3-dihydro-dipicolinic acid. After reaction with succinyl-CoA and opening of the ring, the second amino group is added by transamination, and the succinyl group is added to yield α, ϵ -diaminopimelic acid. This amino acid is unusual in that it has two asymmetic

72. (cont.) Biosynthesis of Amino Acids Derived from Aspartic Acid (cont.)

carbon atoms and thus exists in D-, L-, and meso-stereoisomers. Diaminopimelic acid racemase catalyzes their interconversion. The L-acid is the immediate synthetic product, but it must be converted into the meso-acid before it can be decarboxylated to lysine. Lysine is also unusual because there are two phylogenetically diverse pathways for its biosynthesis. The pathway in bacteria, higher plants, and some algae and fungi is via diaminopimelic acid. In other algae and fungi, the immediate precursor of lysine is α -aminoadipic acid.

Homoserine is formed from aspartic semialdehyde by reduction of the aldehyde group to a primary alcohol by homoserine dehydrogenase and NADH. It is converted to O-succinyl-homoserine and condensed with cysteine (cysteine biosynthesis will be given later) to yield cystathionine in a reaction catalyzed by cystathionine synthetase. Cystathionine is then cleaved in such a way that the S-atom contributed by cysteine now goes with the carbon skeleton of homoserine to become homocysteine. Methionine is finally formed by addition of a methyl group to the -SH group of homocysteine. An example of the transfer of the 1-carbon unit by S-adenosylmethionine has already been given. Here, the agent of 1-carbon transfer

is an example of the second type of compound involved in these reactions, a coenzyme form of the growth factor folic acid. A coenzyme form of vitamin B_{12} also participates in this reaction. The role of folic acid coenzymes in 1-carbon transfer will also be discussed in a later section of this chapter.

The synthesis of threonine proceeds via homoserine and O-homoserine phosphate which is rearranged to threonine in the presence of a pyridoxal phosphate-dependent enzyme. The branched chain amino acid isoleucine is made by decarboxylation of threonine to α -ketobutyric acid, which is

condensed with pyruvic acid to form the branched chain compound α -aceto- α -hydroxybutyric acid. It is then converted to *isoleucine* via the corresponding dihydroxy acid.

Biosynthesis of valine and leucine. The other branched chain amino acids are valine and leucine. They share the common intermediate α -ketoisovaleric acid, which is made from α -acetolactic acid formed as already described by the condensation of pyruvic acid and α -hydroxyethyl-DPT (36). α -Ketoisovaleric acid may be transaminated to valine (73a) or reacted with acetyl-CoA

to form β -hydroxy- β -carboxy-isocaproic acid which is dehydrated, reduced, and transaminated to *leucine* (73b).

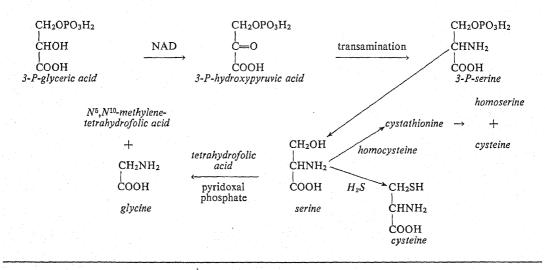

Biosynthesis of serine, glycine, and cysteine. Serine is not only a constituent of bacterial proteins but it is also an intermediate in the synthesis of glycine and cysteine and in the interconversion of methionine and cysteine. Serine is synthesized from the glycolytic intermediate 3-phosphoglyceric acid as shown in 74. It may be converted to glycine in the presence of serine transhydroxymethylase, tetrahydrofolic acid, and pyridoxal phosphate (74). Cysteine may be synthesized directly from serine and H₂S and serine sulfhydrase or indirectly through the intermediation of cystathionine (74).

Biosynthesis of alanine. Alanine may be made in a number of ways (75): transamination of pyruvic acid, reductive amination of pyruvic acid, or the β -decarboxylation of aspartic acid.

Biosynthesis of histidine. Histidine and the purines both have imidazole rings, but they are synthesized by entirely different mechanisms (compare 76 and 85). As shown in 76a, the imidazole ring of histidine contains carbon and nitrogen atoms from 5-phospho- α -ribosyl pyrophosphate, ATP, and glutamine. The first intermediate in histidine biosynthesis to contain an imidazole ring is imidazole glycerol phosphate. It is converted into histidine by the reactions given in 76b.

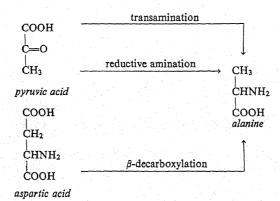

74.

75.

Biosynthesis of Alanine

76.

Biosynthesis of Histidine

Biosynthesis of arginine and proline. These two amino acids are synthesized from glutamic acid through the common intermediate glutamic acid γ -semialdehyde (77a). Proline is made as shown in 77b.

Ornithine, a key intermediate in the synthesis of arginine and a constitutent of some

bacterial cell walls, may be formed by transamination of glutamic γ -semialdehyde (77c) or by a more indirect route involving formation and transamination of N-acetyl-glutamic γ -semialdehyde. Ornithine reacts with carbamyl phosphate synthesized as indicated by the equation in 77d to produce

citrulline, which condenses with aspartic acid to form argininosuccinic acid, which is cleaved to arginine (77c).

Biosynthesis of tyrosine, phenylalanine, and tryptophan. The biosynthetic pathway to the three aromatic amino acids is summarized in 78a and given in detail in 79b, c, d, e. The six-membered ring that is the common precursor of the aromatic ring of each amino acid appears as shikimic acid (78b).

Its 5-phosphate derivative is then converted to chorismic acid which gives rise to prephenic acid, the common intermediate of tyrosine and phenylalanine, and to anthranilic acid, the precursor of tryptophan (78c). Tyrosine and phenylalanine are synthesized as shown in 78d, and the conversion of anthranilic acid to tryptophan is outlined in 78e.

(e)

gram 79 summarizes the biosynthetic pathways just discussed. It immediately becomes obvious that there are three principal pathways from the carbon skeleton of glucose (and other carbohydrates) to the carbon skeletons of the amino acids:

- (1) By way of the tricarboxylic acid cycle to α -ketoglutaric acid and oxalacetic or fumaric acids and thus to glutamic and aspartic acids.
- (2) By way of the pentose phosphate pathway to erythrose-4-phosphate.
- (3) By way of Embden-Meyerhof glycolysis to 3-phosphoglyceric acid and pyruvic acid.

The α -amino group is most commonly derived by:

- (1) Transformation of the carbon skeleton of glutamic or aspartic acids without loss of the α -amino groups.
- (2) Transamination of a precursor of the amino acid, most commonly its α -keto analogue.

With a few important exceptions, the

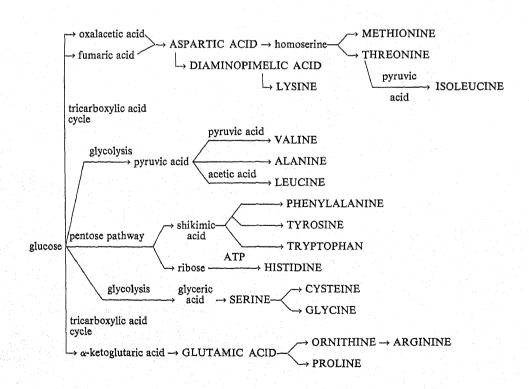

modes of amino acid biosynthesis appear to be the same in all bacteria.

Regulation of amino acid biosynthesis.^{1,8} In general, bacteria synthesize amino acids only when they have to. If a given amino acid is not supplied in the growth medium, a bacterial culture will synthesize it, but if it is added later, de novo synthesis stops at once. This prompt cessation of synthesis is brought about either by end-product inhibition, which is inhibition of the functioning of preexisting enzymes, or by enzyme repression, which is the inhibition of synthesis of new enzyme protein.

In end product inhibition, the final product of a reaction sequence (here an amino acid), characteristically inhibits the enzyme catalyzing the first step in the sequence unique to its synthesis, thus preventing the unnecessary functioning of the entire series of synthetic enzymes. For example, isoleucine strongly inhibits the first unique step in its synthesis, the formation of α -ketobutyric acid (72e), and histidine inhibits the first

79.

Biosynthetic Origin of the Amino Acids

step in its synthesis, the reaction between ATP and 5'-phosphoribosylpyrophosphate (76a). These amino acids act as negative effectors to combine with allosteric sites on the end product-sensitive enzymes to reduce their rates of enzymatic activity.

In repression of enzyme synthesis, the exogenously supplied amino acid acts as a corepressor to initiate a complex series of events that result in inhibition of the transcription of the information for the enzyme protein from DNA to messenger RNA (see Chap. Seven). In this manner, methionine may repress the synthesis of cystathionine synthetase (72d).

Synthesis of peptides. The basic chemical reaction in the synthesis of both peptides and proteins is the synthesis of the peptide

bond (see 80). The equilibrium of this reaction is far to the side of cleavage of the peptide bond, and therefore its synthesis requires an external source of energy. For all the peptides whose synthesis has been studied in detail, this energy is supplied by ATP, which reacts with the carboxyl group of one amino acid (or peptide) to form an amino acyl adenylate (see 81). This carboxyl activation of amino acids by ATP has more than a superficial resemblance to the carboxvl activation of fatty acids by coenzyme A. This activated intermediate then reacts with another amino acid (or another suitable acceptor) to form a new peptide bond (see 82 and the section on protein synthesis below.)

80.

81.

82.

Metabolism of Nucleic Acids, Nucleotides, and Related Substances

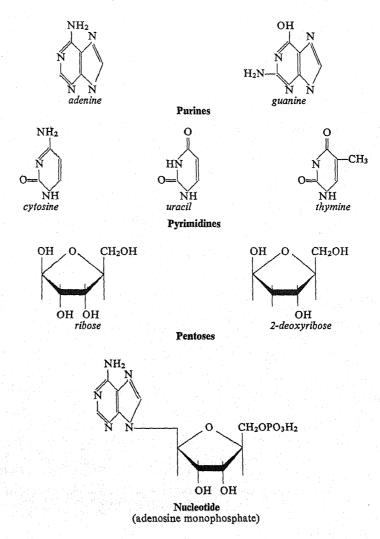

The main representatives of the second great group of naturally occurring nitrogenous substances are the nucleotides and the nucleic acids, which are high molecular weight substances made up of many nucleotide units. A nucleotide is composed of a purine or pyrimidine base, a pentose sugar which is either ribose or deoxyribose, and a molecule of phosphoric acid (see structural formulas in 83). Nucleotides are important

as metabolic intermediates and as portions of coenzymes such as ATP and ADP, NAD and NADP, and CoA. Nucleic acids are of two types. Deoxyribonucleic acid (DNA) contains the pentose deoxyribose and the nitrogen bases adenine, guanine, cytosine, and thymine. Ribonucleic acid (RNA) contains ribose instead of deoxyribose and uracil in place of thymine.

Bacteria and other microorganisms have

83.

Structural Components of Nucleic Acids

large amounts of nucleic acid as compared to higher forms. The nucleic acid content is highly variable and dependent upon the physiological state of the bacterial cell. Nucleic acids may occur in nature in combination with proteins as nucleoproteins. Nucleic acids and the various substances related to them contribute only a small portion of the total nitrogen of the usual bacteriological medium and are not generally a principal source of energy, carbon, or nitrogen. However, certain bacteria vigorously attack purines and pyrimidines and can use them as carbon and nitrogen sources. Also, some fastidious bacteria cannot synthesize all their purines and pyrimidines and must have them supplied in the growth medium.

BREAKDOWN OF NUCLEIC ACIDS³⁵

Nucleoproteins are easily dissociated into nucleic acid and protein, and no specific enzymes for this cleavage have been described. All cells, bacteria included, have numerous enzymes for degrading nucleic acids to smaller fragments. For example, *E. coli* has at least five enzymes that attack DNA. In both DNA and RNA, the nucleotides are linked in polynucleotide chains by 3'-5'-phosphate bridges (shown in 84). Nu-

84.

cleodepolymerases attack intact nucleic acids. Deoxyribonucleases (DNase) hydrolyze phosphate ester linkages in DNA. DNase I of pancreatic origin and streptococcal DNase (streptodornase) split 3'-bonds to yield 5'-mononucleotides and oligonucleotides with 5'-monophosphate ester end groups. On the other hand, DNase II, widely distributed in animal tissues and microorganisms, attacks 5'-bonds to yield 3 -fragments. All these enzymes fail to attack large portions of the DNA molecule, leaving a nonreactive core or limit polynucleotide.

Ribonucleases (RNase) are generally of a single type. They hydrolyze 5'-phosphate esters of pyrimidine nucleotides to yield mononucleotides representing almost all the pyrimidines present, di- and trinucleotides, and a limit polynucleotide.

Phosphodiesterases hydrolyze -O-P-O-bonds in RNA and DNA. RNA is attacked directly, DNA only after exposure to DNase. Phosphomonoesterases hydrolyze nucleotides to nucleosides and inorganic phosphate.

Nucleosides are cleaved to the free purine or pyrimidine base by rupture of the glycosidic bond between the nitrogen atom of the base and the sugar (N-glycosidic bond).

Like the glycosidic bond between two sugars, this N-glycosidic bond may also be split by phosphorylases or transglycosidases. These reactions will be discussed in connection with the synthesis of nucleosides and nucleotides.

Some clostridia, micrococci, and other soil organisms oxidize free purines and pyrimidines and may even be able to use them as sole sources of carbon. Purines are broken down to glycine, acetic acid, formic acid, and CO_2 , while pyrimidines yield β -alanine, lactic acid, acetic acid, and CO_2 .

The free *pyrimidines* are attacked by certain soil microorganisms and oxidized completely to CO₂ and H₂O. Barbituric acid, urea, and malonic acid may be intermediates in the oxidation.

The further metabolism of the *pentoses* released upon breakdown of nucleosides has been previously considered (see Carbohydrate Metabolism).

PRIMARY SYNTHESIS OF PURINES AND PYRIMIDINES

Although purines and pyrimidines are structurally related (see 83), they are synthesized by completely independent pathways.

Synthesis of purines.⁵ In 85 are shown the reactions in the biosynthesis of purines. This biosynthetic pathway leads to inosine

monophosphate, the ribose nucleotide of hypoxanthine. The free purine hypoxanthine is not an intermediate in the synthesis of its nucleotide because the purine ring is built onto ribose-5-phosphate, not vice versa. Following the initial condensation of glycine with 5-phosphoribosylamine, the remainder of the purine ring is formed by the stepwise addition of single atoms of carbon and nitrogen (see 85 and 86).

Synthesis of pyrimidines.³³ Diagram 87

shows how pyrimidines are made. The synthetic mechanisms contrast sharply with those responsible for the production of purines. Aspartic acid and carbamyl phosphate condense to form the skeleton of the pyrimidine ring in one step, the ring is closed, and then the ribose-5-phosphate residue is added by reaction with 5-phospho- α -ribosylpyrophosphate. In an alternate pathway, β -alanine and carbamyl phosphate may condense to form uracil.

FURTHER METABOLISM OF PURINES AND PYRIMIDINES⁴⁰

Bacteria do not independently synthesize each purine and pyrimidine and its corresponding ribonucleosides and deoxyribonucleosides and nucleotides. Instead they carry out extensive interconversions among these different types of purine and pyrimidine derivatives.

A number of different kinds of enzymes are responsible for these interconversions. In the adenine series, as a specific example, adenosine monophosphate is formed from inosine monophosphate by a reaction (see 88) in which aspartic acid is the nitrogen donor (cf. synthesis of arginine from citrulline). It may be split to adenosine and inorganic phosphate by a specific nucleotidase. Adenosine in turn may be cleaved to free adenine and ribose by a nucleosidase. Adenosine monophosphate and adenosine diphosphate are formed by the interaction of ATP and adenosine.

guanosine monophosphate

89.

(a)
$$UMP + ATP \rightarrow UDP + ATP$$

 $2 UDP \rightarrow UTP + UMP$
(b) OH

uridine triphosphate

cytidine triphosphate

Transformations involving alterations in the ring substituents of the purine and pyrimidine bases occur in several ways. The amino group of adenine is deaminated to the hydroxyl group of hypoxanthine in free adenine, adenosine, or adenosine monophosphate. Guanine may be similarly deaminated to xanthine and hypoxanthine reversibly oxidized to xanthine. In the pyrimidines, cytosine is deaminated to uracil and thymidine is demethylated to deoxyuridine.

The principal pathway of deoxyribo-

nucleotide synthesis is the reduction of ribonucleotides to deoxyribonucleotides. In *E. coli*, ribonucleotide diphosphates are reduced to the corresponding deoxyribonucleotide diphosphates by a complex system involving two enzymes, a protein cofactor (thioredoxin), ATP, NADPH, and Mg⁺⁺. In other bacteria, there may also be a requirement for vitamin B₁₂ for the reduction of ribonucleotides to deoxyribonucleotides.

Thymine nucleotides, which exist only as the deoxyribonucleotides, are formed by

methylation of deoxyuridine monophosphate by a folic acid coenzyme and the enzyme thymidylate synthetase (see 90).

REGULATION OF THE BIOSYNTHESIS OF PURINES AND PYRIMIDINES

De novo biosynthesis of purines and pyrimidines in bacteria is strongly inhibited by the end products of these syntheses. Control of purine biosynthesis is achieved by regulation of the interconversion of the nucleotides of guanine, adenine, and inosine (see 88).²⁶ The conversion of inosine monophosphate to guanosine monophosphate is susceptible to end product inhibition by

guanosine monophosphate and repression by guanine, while the reduction of guanosine monophosphate to inosine monophosphate (which can then be aminated to adenosine monophosphate) is inhibited by ATP. Further control is exerted by the requirement of ATP for guanosine monophosphate synthesis and of guanosine triphosphate for synthesis of adenosine monophosphate (88).

Pyrimidine biosynthesis is controlled mainly by the inhibition of aspartyl transcarbamylase, which catalyzes the first step in pyrimidine synthesis, the formation of carbamyl aspartate (87). The most frequent end product inhibitor in bacteria is cytidine monophosphate, but other pyrimidine nucleotides may also be active.

Synthesis of Nucleic Acids and Proteins 9,41

All living cells contain the same low molecular weight building blocks produced by the same biosynthetic pathways. While some small molecules and some pathways occur uniquely in restricted groups of cells, variation in small molecule content is not an important determinant of the individuality of cells. Individuality, which is just as important a biological principle as similarity, is primarily a function of the macromolecules of the cells—DNA, RNA, and protein. They are polymers of common low molecular weight units, the nucleotides and the amino acids, but these units are assembled

in specific linear sequences, and it is in these unique sequential arrangements of a limited number of similar units that biological specificity resides.

The ultimate repositories of biological specificity (i.e., genetic information) are the nucleotide sequences of molecules of DNA, the self-replicating genetic material. In addition to making more molecules like itself, the DNA causes the formation of RNA molecules whose nucleotide sequences carry some of the information possessed by the DNA. These RNA molecules in turn bring about the synthesis of the protein

enzymes required for the energetic and biosynthetic functions of the cell. This section will be limited to a description of the biosynthesis of these macromolecules. Their genetic functioning is the subject of Chapter Seven.

Structure and self-duplication of DNA. According to the model of Watson and Crick, each DNA molecule consists of two polynucleotide strands coiled about a common axis. This double helix is held together by hydrogen bonds between pairs of bases. Because of structural limitations, hydrogen bonds are formed only between adenine and thymine and between guanine and cytosine (91), and ratios of adenine to thymine and of guanine to cytosine are always unity.

In a single strand of DNA, any sequence of nucleotides is possible, and hence a very large number of different sequences, each carrying unique genetic information, is also possible. However, if the order of bases in one strand is specified, the exact sequence in the other chain is simultaneously determined because of the restrictions on base pairing. Thus, each strand in a molecule of DNA is the complement of the other, and each molecule contains two strands but only a single code.

This complementary structure of the double helix is the key to the mechanism of duplication of DNA. According to the model of semiconservative replication, each of the two strands acts as a template for the formation of a new chain with complementary nucleotide sequence. The net result is that two new strands are produced, complementary to each other and each identical with one of the original strands as well.

Synthesis of DNA. Kornberg and his associates have shown that E. coli contains an enzyme, DNA polymerase, which catalyzes the formation of polynucleotides with properties very similar to DNA isolated from natural sources. The polymerization may be visualized as in 92. All four deoxyribonucleoside triphosphates are required. Pyrophosphate is released, and the energy of the nucleoside triphosphates is used to form the polynucleotide chain. Mg++ is necessary for the reaction, and a small amount of polymerized DNA must be present to act as a primer, presumably in the manner just postulated for DNA replication. The amount of new DNA synthesized is many times that added as primer.

The newly synthesized DNA has all the physical properties of natural DNA and is

91.

Pairing of Bases in DNA

triphosphates

hydrolyzed by pancreatic DNase. The ratios of adenine to thymine and of guanine to cytosine are those required by the Watson-Crick model, and the base ratios of the new DNA molecules are very close to those of the primer. It has not been proved that the DNA polymerase of Kornberg is the enzyme that actually precisely duplicates DNA during bacterial reproduction, but it is highly likely that this duplication is carried out by enzymes with similar properties. The DNA of a bacterial virus has recently been made in a biologically active form in vitro through the action of DNA polymerase and one other enzyme.

Synthesis of RNA. Bacteria, plants, and higher animals possess an enzyme, RNA polymerase, which catalyzes the synthesis of RNA from all four ribonucleoside triphosphates, Mn⁺⁺, and a DNA primer (93),

The resemblance to the DNA-synthe-sizing system just described is striking. Here DNA also acts as a template for polynucleotide assembly. However, since the building materials at hand are ribonucleotides, RNA, not DNA, is produced. The template role of the primer DNA is clearly shown by observations that the composition of the newly synthesized RNA closely approximates that of the DNA primer, even when DNA molecules of widely varying base ratios are employed.

Although it appears that in vitro both

strands of the DNA helix may serve as templates for the synthesis of RNA, only one of the DNA strands is probably copied in the intact bacterial cell. RNA synthesized on a DNA template and carrying the genetic information of that portion of the DNA molecule to which it is complementary is called *messenger RNA* (mRNA). The process of transferring information from DNA to RNA is called *transcription*.

Ribopolynucleotides are also synthesized by the widely distributed polynucleotide phosphorylase. The enzyme polymerizes single ribonucleotide diphosphates or mixtures of them (94). Thus, polymers containing one, two, three, or four nitrogen bases may be synthesized. When the polynucleotide phosphorylase is purified, a primer becomes necessary. The requirement is for an oligonucleotide with a free 3'-hydroxyl group to which the new nucleotide units are added.

The genetic code.⁹ The information required for the insertion of a specific amino acid into a specific position in a polypeptide chain is contained in three successive nucleotide residues of a molecule of DNA and its complementary mRNA; that is, the genetic code consists of nucleotide triplets. The ultimate repository of information is in the triplets of DNA, but the complementary triplets, or codons, of mRNA are usually used to formulate the genetic code, which

93.

$$\begin{bmatrix} n_1 UPPP \\ n_2 GPPP \\ n_1 APPP \\ n_2 CPPP \end{bmatrix} \xrightarrow{\begin{subarray}{c} DNA \\ template, \\ Mg^{++} \end{subarray}} \begin{bmatrix} UP \\ GP \\ AP \\ CP \end{bmatrix} + 2(n_1 + n_2)PP \\ 2n_1 + 2n_2 \\ ribonucleoside \\ triphosphates \end{bmatrix}$$

94

$$\begin{bmatrix} n_{l}UPP \\ n_{2}GPP \\ n_{3}APP \\ n_{4}CPP \end{bmatrix} \xrightarrow{Mg^{++}} \begin{bmatrix} UP \\ GP \\ AP \\ CP \end{bmatrix} + (n_{l} + n_{2} + n_{3} + n_{4})P$$

$$= n_{l} + n_{2} + n_{3} + n_{4}$$

may be conveniently tabulated as shown in 95. This shows the best currently available allocation of the codons and is based mainly on results obtained with *E. coli*. Thus, the codon specifying phenylalanine is UUU, that specifying tyrosine is UAU or UAC, etc.

Synthesis of proteins. Protein synthesis requires a source of energy for formation of the peptide bond and a mechanism for ordering the sequence of amino acids in the polypeptide chain. As in the synthesis of DNA and RNA, the energy is supplied by a nucleoside triphosphate and the template by a polynucleotide. However, since proteins are made up of amino acids, not nucleotides, both processes are more indirect and more complicated.

Amino acids are activated in the form of aminoacyl adenylates by specific activating enzymes associated with the cytoplasmic membrane and soluble fraction of the bacterial cell. There is at least one activating enzyme for each amino acid. The first step is:

 $\frac{Mg^{++}}{amino\ acid + ATP + E} = \frac{(amino\ acyl-AMP-E) + PP}{amino\ acyl-AMP-E}$

	2nd								
1st	U	С	A	G	3rd

G	val	ala	asp	gly	U				
	val	ala	asp	gly	C				
	val	ala	glu	gly	A				
	val	ala	glu	gly	G				

Key: U = uracil, C = cytosine, A = adenine, G = gua-

The next step is the transfer of the activated amino acid to a special kind of RNA, transfer RNA (tRNA).

amino acyl - tRNA + AMP + E

There is at least one tRNA for each amino acid. They are small polynucleotides, about 70 to 80 nucleotides in length, and the complete nucleotide sequence is known for a few of them. The tRNA molecules have two recognition sites, the one just described for recognizing the activating enzyme and another separate site, the coding site, for binding to a specific codon in the mRNA strand. All amino acids are linked to their transfer RNA's through esterification to the 2'- or 3'-hydroxyl groups of a terminal adenosine moiety.

Polypeptide chains are assembled on the surface of the *ribosomes* (see Chap. Three). These cytoplasmic particles contain about equal amounts of protein and a third species of RNA, *ribosomal RNA* (rRNA). In *E. coli*, the bacterium in which protein synthesis has been most extensively studied, the ribosomal particles involved in protein synthesis are 30 S and 50 S units. In the presence of mRNA, these units attach themselves to the polynucleotide strand to form polyribosomes or polysomes:

$$[30S + 50S]_x + mRNA \rightarrow polysome$$

The value of x is in the range of 5 to 20. The ribosomes of procaryotic cells must differ in subtle ways from those of eucaryotic cells, because protein synthesis on procaryotic ribosomes is much more susceptible to inhibition by antibiotics such as chloramphenical and the tetracyclines.

Although mRNA is the template on which the amino acids are assembled to be formed into polypeptide chains, it cannot function directly because polypeptides cannot be formed on polynucleotide templates. This difficulty is circumvented by the structure of tRNA. The coding site of the tRNA acts as an adapter; that is, each tRNA has a coding site complementary to a specific codon in the mRNA strand and binds to it, thus locating its activated amino acid in a definite relationship to other amino acids similarly bound. This transfer of information is known as translation.

During synthesis of a polypeptide chain,

ala = alanine, arg = arginine, asp = aspartic acid, aspn = asparagine, cys = cysteine, glu = glutamic acid, glun = glutamine, gly = glycine, his = histidine, ileu = isoleucine, leu = leucine, lys = lysine, met = methionine, phe = phenylalanine, pro = proline, ser = serine, thr = threonine, try = tryptophan, tyr = tyrosine, val = valine.

the mRNA moves across the ribosomes of its polysome unit to successively expose its codons, which bind in proper sequence the appropriate amino acyl-tRNA complexes. Polypeptide chains are always synthesized from their N-terminal ends.

The mechanisms of the movement of the mRNA across the ribosomes and of the formation of the peptide bonds of the polypeptide chain are not well understood. The energy for moving the mRNA strand and for bringing the amino acyl-tRNA into its proper binding position is probably supplied by the hydrolysis of guanosine triphosphate, which is required in all protein-synthesizing systems so far studied. The energy for peptide bond formation is provided by hydrolysis of the amino acyl complexes at the moment of peptide bond synthesis. This reaction is catalyzed by a specific enzyme (transfer factor).

There must be specific mechanisms for starting and stopping the synthesis of a polypeptide chain. In E. coli, most poly-

peptide chains, at the moment of their elaboration, are made with the common N-terminal sequence shown in 96, although all these residues may be removed in the final fashioning of the biologically active protein. It is highly likely that the codon that recognizes N-formyl-methionine-tRNA is responsible for chain initiation, but the structure of this codon is still in doubt. There are two codons that may, in certain systems, result in chain termination, apparently because they specify no amino acid at all. These are the amber (UAG) and ochre (UAA) triplets (see 95). These may be universally occurring natural chain terminators, but this is not certain.

The complicated interrelationships in the biosynthesis of DNA, RNA, and protein are shown in a greatly simplified and abbreviated diagram (97). Note that the ultimate source of genetic information is the sequence of bases in DNA and that the ultimate source of biosynthetic energy is the high energy bonds of ATP.

96.

97.

dNTP = deoxyribonucleoside triphosphate; NTP = ribonucleoside triphosphate.

Nutrition of Bacteria

In order to synthesize the many components of their protoplasm and thus to grow and multiply, bacteria must be supplied with a medium containing the proper chemical constituents for supporting the necessary biosynthetic reactions. The chemical substances which must be furnished bacteria in order that they may grow and multiply are known as their growth requirements or nutritional requirements. These nutritional factors are usually classified as:

- (1) Compounds required as energy sources.
- (2) Compounds required as building stones for the synthesis of new cell material
 - (a) Compounds required as carbon sources.
 - (b) Compounds required as nitrogen sources.
 - (c) Organic compounds required in their intact form as growth factors.
- (3) Inorganic ions required for metabolism and growth.

Given these necessary factors, bacteria will grow in the proper physicochemical environment (favorable temperature, pH, O₂ tension, etc.). Different kinds of bacteria have widely varying growth requirements, and even the same bacterium may have variable nutritional needs, depending upon the conditions of growth and the presence or absence of other substances in the medium.

Many aspects of bacterial nutrition have already been treated in terms of the metabolic functioning of the various nutritional factors. In particular, the sources of energy, carbon, and nitrogen have been repeatedly discussed and will not be considered further here. Much has also been said about the metabolic function of growth factors, so the chief object of this section will be to collect and summarize the basic information about the role of growth factors in bacterial nutrition

Growth factors. A growth factor may be defined as an organic compound which a bacterium needs for growth yet cannot synthesize. Since all cells have essentially the same chemical make-up, it follows that bacterium A, which does not need a growth factor required by bacterium B, lacks this requirement because it can synthesize the factor in question. Thus, L. casei requires folic acid, while E. coli does not because it makes its own folic acid.

It is generally believed that the variations in nutritional requirement observed among

presently existing groups of bacteria have arisen by loss of synthetic ability through genetic modifications. This idea receives direct experimental support from work in bacterial genetics (Chap. Seven) which has demonstrated that mutations in bacteria cause the loss of ability to synthesize those compounds—the B vitamins, amino acids, purines, and pyrimidines—which are growth factors for naturally occurring bacterial populations.

Growth factors are of two main types: (1) those required in minute amounts and which function catalytically as portions of enzyme systems: the B vitamins are the principal representatives of this type; (2) those required in substantially large quantities and which are incorporated directly or with only minor modifications into cell material: the amino acids, purines, and pyrimidines are the chief examples of this kind of growth factor.

An organism may exhibit an absolute requirement for a growth factor; i.e., no growth at all occurs in its absence. On the other hand, a growth factor may be stimulatory; i.e., limited growth without the factor is sharply increased upon its addition.

The vitamin B group.³⁴ The B-complex vitamins, or the vitamin B group, are low molecular weight, water-soluble organic compounds which are universal constituents of all living cells, in which they function as coenzymes or portions of coenzymes. It is customary to designate as the vitamin the simplest compound which, when supplied to the cell, allows it to synthesize the coenzyme. Thus, pantothenic acid is a B vitamin whose coenzyme form is CoA.

Since the B vitamins function catalytically, they promote bacterial growth in very low concentrations. The B vitamins are usually supplied to bacteria in concentrations of about 10^{-6} to 10^{-10} M or 0.0001 to 0.00000001 mg. per ml. of medium. Vitamin B₁₂ and biotin are generally required in smallest amount, nicotinic acid and riboflavin in the largest.

The accompanying table summarizes the metabolic function of the B vitamins.

Thiamin. Thiamin is one of the earliest recognized and most frequently required bacterial growth factors. It is synthesized by condensation of the thiazole portion

Metabolic Functions of the Vitamin B Group

B VITAMIN	TYPICAL ORGANISMS REQUIRING IT	COENZYME FORM	METABOLIC FUNCTIONS
Thiamin	Staph, aureus L. fermenti	DPT	Activation of keto acids and keto sugars; transfer of 2-carbon units
Nicotinic acid	L. arabinosus Pr. vulgaris	NAD and NADP	Hydrogen transfer
Riboflavin	L. casei Str. lactis	Riboflavin-5-P Flavin-adenine- dinucleotide	Hydrogen transfer
Vitamin B ₆			
pyridoxal pyridoxal or	L. casei {Cl. welchii	Pyridoxal-P Pyridoxamine-P	Decarboxylation, deamination, transamination, and racemization
pyridoxamine Pantothenic acid	\Str. fecalis Brucella abortus Pro. morganii	CoA 4'-Phosphopantetheine	of amino acids Acyl activation and transfer Fatty acid synthesis
p-Aminobenzoic acid	Cl. acetobutylicum Acetobacter suboxydans	Tetrahydrofolic acid	1-carbon-transfer
Folic acid	L. casei Cl. tetani	Tetrahydrofolic acid	r-carbon-transici
Biotin	Leuc. mesenteroides Cl. tetani L. arabinosus	Biotin-CO ₂	CO ₂ fixation, fatty acid synthesis
Vitamin B ₁₂	L. leichmannii L. lactis	$5'$ -deoxyadenosyl- B_{12} , methyl- B_{12}	1-carbon transfer Synthesis of deoxyribosides

and the pyrimidine portion of the molecule (see 98).

As expected from the way thiamin is synthesized, some bacteria require the thiazole alone, the pyrimidine alone, both thiazole and pyrimidine, or intact thiamin. The biosynthetic origin of the thiazole and pyrimidine intermediates is unknown. So far, no microorganism has been found with a requirement for the whole coenzyme, DPT.

Nicotinic acid (niacin). Nicotinic acid and nicotinamide are the growth factors

usually required by bacteria for the synthesis of NAD and NADP (see 4 for the

structural formulas). However, many species of the genus Hemophilus cannot utilize nicotinic acid or its amide for the

98.

synthesis of NAD and NADP and must be supplied with the intact coenzymes or with nicotinamide riboside. The probable metabolic pathway from nicotinic acid to NAD and NADP is shown in 99.

Riboflavin. Riboflavin as a growth factor resembles nicotinic acid, not in structure, but in the functioning of its coenzyme in hydrogen transfer and in the mode of synthesis of the coenzyme from the vitamin. Riboflavin has the structure shown in 100.

It is composed of a nitrogenous base, 6.7-dimethylisoalloxazine (flavin) and ribitol, the sugar alcohol corresponding to ribose, and is, therefore, comparable in structure to nicotinamide riboside. Its coenzyme forms are riboflavin-5-phosphate and flavin adenine dinucleotide (see 6 for structures).

The biosynthesis of the isoalloxazine ring is closely related to that of the purine ring. Note that the portion of the isoalloxazine ring lying to the right of the dotted line in 100 is identical with that of the purine ring (minus carbon 8). The riboflavin coenzymes are synthesized in a manner quite similar to that of the nicotinic acid coenzvmes (see 101).

Vitamin B_6 . Vitamin B_6 is a collective term for several closely related factors (structural formulas in 102). Of these, pyridoxal phosphate and pyridoxamine phosphate are the coenzyme forms (see Transamination). For higher animals, yeasts and molds, pyridoxine, pyridoxal, and pyridoxamine are of equal activity as growth factors. but for most bacteria, either pyridoxal or pyridoxamine is required. Some, such as

99.

(1) nicotinic acid + NH₃ → nicotinamide

(2) nicotinamide + ribose-1-P → nicotinamide riboside + H₃PO₄

(3) nicotinamide riboside + ATP → nicotinamide-5-P + ADP (4) nicotinamide-5-P + ATP → NAD + P-P

(5) NAD + ATP \rightarrow NADP + ADP

100.

pyridoxamine phosphate

pyridoxal phosphate

NUTRITION 171

L. casei, respond only to pyridoxal, while a few strains of lactobacilli require either pyridoxal phosphate or pyridoxamine phosphate.

Vitamin B_6 is a good example of a growth factor which is highly stimulatory, but not absolutely required. Most yeasts and lactobacilli such as L. arabinosus will produce heavy growth in the absence of vitamin B_6 , but in its presence the same amount of growth is achieved in a much shorter time.

Since it has been repeatedly demonstrated that pyridoxal phosphate is closely associated with almost every phase of amino acid metabolism, it is not surprising that the quantitative pyridoxine requirement depends upon the amino acid composition of the medium. This is particularly true for the lactobacilli which require many amino acids as growth factors. L. arabinosus can apparently synthesize a small amount of vitamin B₆, enough for growth on a medium rich in amino acids, such as a casein hydrolysate. However, omission of these amino acids forces the organism to make them itself, and it cannot synthesize enough vitamin B₆ to catalyze the reactions involved. Therefore, on a medium poor in amino acids, L. arabinosus must have additional vitamin B₆ for growth.

Pantothenic acid. Pantothenic acid is required for the growth of many bacteria. Its principal function is as a part of CoA, the coenzyme of acetyl transfer. It is synthesized by the union of β -alanine and pantoic acid, which are derived from aspartic acid and valine, respectively (see 103).

As with thiamin, some organisms require only one portion of the vitamin (β -alanine or pantoic acid) for growth, but the lactobacilli and many other bacteria can utilize only intact pantothenic acid.

One lactobacillus, L. bulgaricus, requires a higher form of pantothenic acid, pantetheine, formed from pantothenic acid and cysteine (see formula 104). It is very probable that pantetheine is an intermediate in the biosynthesis of CoA (see 35 and 105). 4'-Phosphopantetheine is the coenzyme of fatty acid synthetase. CoA is not an absolute growth requirement for any microorganism, but it is a stimulatory factor for Acetobacter suboxydans.

p-Aminobenzoic acid and the folic acid group. The role of folic acid in 1-carbon transfer has already been discussed in connection with the metabolism of amino acids and of purines and pyrimidines. Each member of the folic acid group contains p-aminobenzoic acid and a pteridine nucleus, and

103.

104.

pantothenic acid

β-mercaptoethanolamine

Pantetheine

they are metabolically interconverted by many bacteria. The precursor of *p*-aminobenzoic acid is 5-P-shikimic acid (see 78). Its amino group is donated by glutamine. The pteridine ring has a close structural resemblance to the purine and isoalloxazine rings, and all three are synthesized by related mechanisms.

p-Aminobenzoic acid is incorporated into folic acid, and the sulfonamides inhibit bacterial growth by preventing the incorporation.

Many bacteria, such as *E. coli*, do not require *p*-aminobenzoic acid or any of its higher forms, but its importance in their metabolism is easily demonstrated by its ability to overcome the growth inhibition produced by sulfonamides. Others, such as *L. arabinosus*, require preformed *p*-aminobenzoic acid but can synthesize the remainder of the folic acid coenzyme themselves. How-

ever, certain lactobacilli and clostridia also lack the ability to synthesize other portions of the folic acid molecule as well. Thus, Str. fecalis requires a growth factor of at least the complexity of pteroic acid, in which the bond between p-aminobenzoic acid and the pteridine nucleus has already been formed. L. casei lacks, in addition, the ability to join glutamic acid to pteroic acid and, therefore, requires pteroylglutamic acid as a growth factor. Finally, Pediococcus cerevisiae needs leucovorin, which differs from pteroylglutamic acid in the possession of a formyl group and a reduced pteridine nucleus. There are also many other forms of folic acid.

The coenzyme forms of folic acid are tetrahydrofolic acid and derivatives of this compound with active 1-carbon groups. Their probable biosynthetic origin is shown in the accompanying diagram (106). A gen-

106.

Biosynthesis of Folic Acid Coenzymes

NUTRITION 173

eralized formulation of the role of folic acid coenzymes in 1-carbon transfer is shown in 107. Other evidence also suggests that folic acid may be active in the synthesis of the amino acids histidine, threonine, and leucine.

Just as the vitamin B_6 requirement is profoundly influenced by the amino acid composition of the medium, so may the p-aminobenzoic acid or folic acid requirement be reduced or abolished by addition of the purines, pyrimidines, and amino acids which are synthesized in folic acid-requiring reactions. These same substances will also counteract the growth-inhibiting action of sulfonamides on organisms which require neither p-aminobenzoic acid nor folic acid.

Biotin. Biotin is a growth factor for many different types of microorganisms and for higher animals. It is likely that the pathway of biotin biosynthesis is as shown in 108.

In combination with a specific enzyme protein, biotin reacts with CO_2 to form an enzyme-biotin- CO_2 complex, which, as already discussed, acts as a CO_2 donor in several heterotrophic carbon dioxide fixations. The structure of biotin- CO_2 is shown in 109.

The biotin requirement of microorganisms, like that for the other B vitamins, is markedly affected by the presence of substances which are synthesized in biotin-dependent reactions. The best example of this dependency is furnished by the interrelationship of biotin, aspartic acid, and oleic acid in the nutrition of *L. arabinosus*. The bacteria will grow without either aspartic acid or oleic acid if the biotin concentration is high. If aspartic acid is also added, the biotin requirement is cut ten-fold; if both aspartic and oleic acids are added, *L. arabinosus* grows without any biotin at all in the medium.

Vitamin B_{12} .³⁹ This vitamin is a large and complex molecule consisting of (1) a complex ring system, the corrin moiety, closely related to the porphyrins of the cytochromes, chlorophyll, and hemoglobin and synthesized by similar mechanisms, (2) an atom of trivalent cobalt bound to the porphyrin-like structure in much the same fashion as the iron in hemoglobin, (3) a cyanide ion linked to the cobalt ion, (4) a nucleotide containing a substituted benzimidazole as the base, and (5) a molecule of an amino alcohol which is bonded to both the nucleo-

107.

(2) tetrahydrofolic acid-C₁ + acceptor = tetrahydrofolic acid + acceptor-C₁

108.

109.

tide phosphorus and a side chain of the corrin moiety (see 110).

Although perhaps the greatest interest in vitamin B₁₂ stems from its ability to combat certain human anemias, it is required by many lactobacilli, and numerous enzymatic reactions in bacteria are dependent on coenzyme forms of vitamin B_{12} . For example, the previously discussed conversion of methylmalonyl-CoA to succinyl-CoA (49) and the reduction of ribonucleoside diphosphates to their deoxyribonucleoside counterparts require the participation of 5'-deoxyadenosyl-B₁₂ in which the CN⁻ of vitamin B₁₂ has been replaced with a 5'-deoxyadenosyl group derived from ATP. Another vitamin B₁₂ coenzyme, methyl-B₁₂, together with N5-methyltetrahydrofolic acid, is required for the methylation of homocysteine to methionine (72d).

Amino acids.²⁸ Many bacteria can synthesize all their amino acids themselves

(E. coli) or can synthesize all but one or two (Salmonella typhi requires only tryptophan). In general, the gram-negative organisms are potent amino acid synthesizers and require no preformed amino acids or only a limited number. The ability of gram-positive bacteria to synthesize amino acids is much more limited, particularly among the lactic acid bacteria. Leuc. mesenteroides requires, for example, 17 different amino acids.

Amino acids are required in substantially higher concentrations than are the B vitamins, roughly about 10⁻⁴ M or about 0.01 mg. per ml. of medium.

Amino acid assimilation. Since grampositive organisms lack the ability to synthesize many amino acids, they must take them up or assimilate them from the medium. Many gram-positive bacteria, perhaps in compensation for their lack of synthetic powers, have developed efficient mechan-

110.

cyanocobalamin

Vitamin B₁₂

NUTRITION 175

isms for assimilating and concentrating the amino acids of the medium within their cells. Thus, Staphylococcus aureus can assimilate glutamic acid until the intracellular amino acid level is 400 times that of the external medium. The exact mechanism by which this concentration is achieved is unknown, but it is an active, energy-requiring process. Not all amino acids are concentrated within the cell to the same degree as glutamic acid. Lysine, for example, enters the cell only by diffusion and thus never attains an intracellular concentration higher than that of the medium.

Factors influencing the requirement for amino acids. Although the amino acid requirement of an organism depends ultimately on its genetic composition, which in turn defines the range of its synthetic ability, the expression of this requirement varies under different conditions of growth.

- (1) THE EFFECT OF VITAMINS. The modification of the requirement for vitamin B₆, biotin, and folic acid by the presence of amino acids in the medium has already been discussed. It is obvious that the reverse also holds true. Thus, pyridoxal may alter the requirement for D-alanine, biotin for aspartic acid, folic acid for methionine, and so on.
- (2) THE EFFECT OF OTHER AMINO ACIDS. Many amino acids interfere with or antagonize the metabolism of other amino acids. For example, Bacillus anthracis grows without either leucine or valine. Yet if leucine is added, growth is inhibited, but is restored in the presence of both leucine and valine. These amino acids have similar structures, and it is probable that leucine acts as an inhibitor for the synthesis of valine, thus preventing growth until valine is also added. Similarly, tyrosine prevents the synthesis of the closely related phenylalanine by E. coli. These are examples of antagonisms between naturally occurring essential metabolites of the same nature as the antagonism between p-aminobenzoic acid and the sulfonamides. Many other examples of amino acid antagonisms have been reported.

The amino acid requirement for specific functions, such as the synthesis of an enzyme, may be different from those for growth. E. coli, for example, needs exogenous methionine, tyrosine, and asparagine to make arginine decarboxylase.

Purines and pyrimidines. Many bacteria,

especially the lactobacilli, are unable to synthesize the purine and pyrimidine bases which they need as constituents of their nucleic acids, nucleotides, etc. In general, the synthetic block appears to be in the formation of the purine or pyrimidine nucleus, and the majority of nitrogen-base requiring organisms are still capable of some interconversion of the bases. Thus, L. arabinosus can utilize either adenine. guanine, hypoxanthine, or xanthine as its sole purine source. Other organisms are more exacting and respond much more to one purine than to another. The classic example of a pyrimidine requirement is that of Staph. aureus for uracil.

Purine and pyrimidine requirements are modified by the same type of factors that affect the amino acid requirement. The interrelation between folic acid and thymine and the purines has already been mentioned, as has the interchangeability of vitamin B_{12} and thymidine and other deoxyribosides in the nutrition of the same bacteria. Antagonisms between the purine bases also affect the purine requirement. In particular, adenine and guanine each interfere with the metabolism of the other in a number of bacteria and yeasts.

The inorganic elements. The elementary constituents of the bacterial cell other than the carbon, hydrogen, oxygen, and nitrogen present in organic compounds must also be supplied in an adequate nutritional medium. It is customary to include in bacteriological mediums phosphate, sulfate, potassium, calcium, magnesium, manganous, and ferric ions. The need for these ions in metabolism is obvious. Organic phosphate compounds play a role in almost every phase of intermediary metabolism, and as phospholipids and nucleic acids are a part of the structural framework of the cell. Sulfate, or some form of sulfur, is needed for synthesis of the sulfur amino acids. Potassium, calcium, magnesium, and manganous ions are cofactors or activators in many enzyme sys-

Some organisms also have more specific inorganic requirements. Thus, the diphtheria bacillus gives optimum toxin production with an iron concentration of about 0.00014 mg. per ml. of medium. Higher or lower concentrations inhibit toxin production without affecting growth. Azotobacter specifically requires molybdenum for some phases of nitrogen fixation.

Undoubtedly other inorganic ions also appear in bacterial protoplasm and, therefore, must be present in the medium. However, it is very hard to show clearly that a particular ion is absolutely required for growth. This is because the inorganic ions are universal contaminants of all types of materials, so that it is almost impossible to free mediums of the last traces of an ion.

Microbiological assay.²⁰ An important practical application of the elucidation of the growth factor requirements of bacteria has been the development of methods for quantitative determination of vitamins and amino acids in terms of the growth response of microorganisms. The high degree of specificity and sensitivity attainable in microbiological assay have made this technique an invaluable tool in many fields of biological research.

PHYSICAL AGENTS, BACTERICIDAL SUBSTANCES (DISINFECTANTS), AND CHEMOTHERAPEUTIC DRUGS

The separation of the environmental factors, that so profoundly affect the life processes of living cells, into two groups, one designated physical and the other chemical, is undoubtedly artificial in many instances. It is often difficult, if not impossible, to differentiate the physical from the chemical; the lethal effect of a bactericidal substance, for example, may be a result of a combination of both physical and chemical activity or its mode of action may lie in the borderland of surface and physical chemistry. Nevertheless, such a separation has a certain reality and is useful for purposes of exposition.

Bacteria, like all other living organisms, consist of protoplasm, a delicately balanced, heterogeneous mixture of various substances in colloidal and true solution. The disturbance of this equilibrium through, for instance, the precipitation of constituent protein is incompatible with the continuation of the complex phenomena of life, and the cell dies. On the other hand, the environment, when favorable, not only does not destroy this equilibrium but makes possible its continuation through growth and multiplication of the organisms. Bacteria, like other organisms, are creatures of their environment; under favorable conditions they multiply rapidly, and under unfavorable conditions either die or remain dormant in a viable state until another opportunity for growth presents itself. In general, they are much more resistant to unfavorable circumstances than are most higher forms of life. A part of this resistance is, of course, a result of the ability of some bacteria to form spores which are relatively highly resistant, but the vegetative cells are considerably more resistant than are the cells of multicellular organisms.

The inactivation of viruses tends to be set somewhat apart since they consist of nucleic acid protected, in the vegetative form, by a protein coat whose contribution to viral replication is not altogether clear, and they are not physiologically complete units like the bacteria. ^{26, 73} Thus bacteria could not survive the treatment with 50 per cent phenol, a good disinfectant, used to extract infectious ribonucleic acid from many RNA-containing viruses, nor are bacteria or vegetative viruses destroyed by treatment with ribonuclease as is infectious RNA.

It is not possible to differentiate sharply between these favorable and unfavorable factors. The congruity of a given environmental factor with the protoplasmic equilibrium that is life is largely a quantitative rather than a qualitative phenomenon. Although high temperatures destroy bacteria, a certain degree of warmth is essential to their growth. Distilled water is toxic to many microorganisms, yet multiplication takes place only in the presence of adequate amounts of moisture. Even highly active bactericidal chemicals often markedly stimulate growth of bacteria, when in sufficiently low concentrations.

Physical Agents

Temperature relations.80 Bacteria as a group will thrive under a relatively wide range of temperature conditions. Some of the more hardy, such as Bacillus subtilis, will grow throughout the range of 6° to 50° C. Others, such as many of the pathogenic forms, are able to grow over a much narrower range, and some of the more fragile organisms will grow only at body temperature, i.e., 37° C., or very close to this temperature. For all these organisms, however, three temperature limits may be distinguished. There is the minimum or lowest temperature at which a given organism will grow, an optimum or temperature of most luxuriant growth, and a maximum, the highest temperature at which growth can take place. The position of these three points differs greatly among different species of bacteria. In general, those organisms whose natural habitat is soil or water have optimum temperatures of 22° to 28° C., while those which, presumably as a result of adaptation to a parasitic mode of existence, cannot survive outside the animal body, have an optimum of 37° C.

There are, however, bacteria whose optimum temperatures differ considerably from these. Organisms have been found whose optimum temperatures are from 15° to 20° C., and they have been termed psychrophiles or cold-loving organisms. Others having optimum temperatures of 55° to 65° C. may be found in the soil and hot springs and are called thermophiles. The great majority of bacteria have optimum temperatures which lie between these two extremes and, in this terminology, are designated as mesophiles.

The optimum temperature for given species of bacteria is generally considered to be that temperature at which the organisms grow "best." The criteria of bacterial growth have been discussed elsewhere (Chap. Four). So far as the effects of incubation temperatures are concerned, those optimum for growth in terms of rapidity of cell division are not always the same as those optimum for the attainment of maximum numbers of cells per unit volume. A culture grown at a temperature at which cell multiplication is most rapid will not attain as high a peak in numbers as a culture of the same organism growing more

slowly at a lower temperature. 89, 93, 94 At higher temperatures oxygen is rapidly depleted to growth-limiting levels, and higher yields of cells grown at lower temperatures may be attributed to less rapid utilization coupled with greater solubility and availability of oxygen. 86

Other physiological activities of the cell appear to have optimum temperatures that differ from those which are optimum for multiplication. A given sugar may be fermented to a greater extent, more slowly, when the culture is incubated at a temperature somewhat below that optimum for cell division. Similarly, the anthrax bacillus forms spores most abundantly at 30° to 32° C., while its optimum for vegetative multiplication is 37° C.

The continued growth of bacteria at temperatures somewhat higher than optimum may induce physiological changes of a temporary or permanent character. Serratia marcescens, for example, fails to form its characteristic red pigment when incubated at temperatures higher than 30° C., but the change is temporary, for subcultures incubated at lower temperatures form pigment normally regardless of how many transfers have been grown at the higher temperature. The anthrax bacillus, on the other hand, when grown for several transfers at 42° C., loses its ability to form spores and becomes avirulent—a change that appears to be permanent. Incubation or storage of bacterial cultures at temperatures lower than optimum does not result in such qualitative physiological changes; the metabolic activities of the organisms are slowed down and at temperatures below the minimum for growth the bacteria become dormant.

The mechanisms determining the optimum, minimum, and maximum temperatures of bacteria are obscure. In some cases they may be dependent upon other environmental factors. Thus, while many of the thermophilic bacteria are able to grow only at temperatures above 50° C. when in contact with air, they are able under anaerobic conditions to grow at the ordinary incubator temperature (37° C.) or even as low as 34° C. There is evidence too that the maximum growth temperatures of bacteria bear a definite relationship to the minimum temperature of destruction of respiratory enzymes.

179

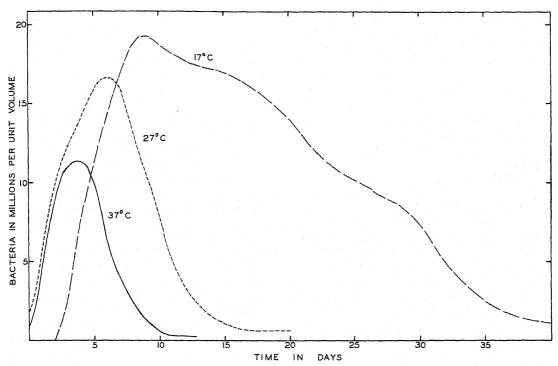

Figure 46. The effect of different temperatures of incubation on broth cultures of *Staphylococcus aureus*. (After Graham-Smith.)

The enzymes of thermophilic bacteria do not, however, have unusually high inactivation temperatures; rather, thermophilic growth is possible because the rate of synthesis of enzymes and other thermolabile cell constituents exceeds the rate of their destruction at the high environmental temperatures.⁴ The upper temperature limit of growth has been found to be 73° C.⁵⁶

The lethal effects of heat. Bacteria are readily killed by heat, and the utilization of heat in one form or another is one of the most convenient means of their destruction. The lethal effects of heat are markedly influenced by the amount of moisture present. and so-called moist heat is a much more effective killing agent than dry heat. The resistance of bacteria to moist heat differs somewhat from species to species, the pathogenic forms being in general somewhat less resistant. The resistance of a given species is influenced by two important factors: the ability of the organisms to form spores and the previous history of the culture. Spores are always much more resistant than vegetative forms. Some species when in the spore stage can withstand the temperature of boiling water for upward of 16 hours. The vegetative forms of most bacteria, on the other

hand, are killed at 55° to 58° C. by 30 minutes' exposure in the presence of moisture.

The time and temperature of incubation influence, to some extent, the heat resistance of vegetative cells. Actively growing cultures in the logarithmic phase are generally somewhat less resistant than are cells removed from cultures containing maximum numbers of viable organisms. The temperature of incubation appears to affect thermal resistance somewhat, in that cultures grown at and above the optimum temperature are more resistant than cultures grown at suboptimal temperatures.

The pH of the liquid in which the microorganisms are suspended is of considerable quantitative importance. Deviations from neutrality increase, to a marked degree, the rate at which a given temperature kills bacteria. Acid foods, such as tomatoes, are more readily preserved than foods which have a neutral reaction. Likewise, the addition of sodium carbonate to water in which surgical instruments are boiled increases the efficiency of the heat and at the same time tends to reduce rusting.

The death of an organism from heat is determined not only by the temperature reached but also by the time of exposure.

The tubercle bacillus, for example, is killed by 30 minutes' exposure at 58° C., 20 minutes' at 59° C., and 2 minutes' at 65° C. One may, therefore, determine the thermal death point of a given bacterium by exposure to varied degrees of heat for a constant time, or, similarly, a thermal death time may be determined by holding the temperature constant and varying the time of exposure. Both are useful, the latter possibly somewhat more so.

The effect of heat seems to be injurious even when bacteria are not killed, since the cells that have been heated appear to require a longer period of germination. Exposure to sublethal heat prolongs the latent period preceding cell division without affecting the rate of regeneration of the respiratory function, with no evidence of a period of "recovery" distinct from growth. On the other hand, sublethal heating of bacterial spores often has the effect of accelerating germination.

Sterilization by heat. The application of moist heat to the destruction of bacteria may take several forms. Sterilization by means of steam under pressure is the most efficient of these, because it makes possible temperatures higher than 100° C. in the presence of moisture. At 15 pounds pressure, for example, the temperature will be 121.3° C., and at 20 pounds, 126.2° C. As a rule, exposure to 120° C. for 15 minutes suffices for the complete destruction of both vegetative and spore forms of bacteria, although rarely highly resistant spores may be found that are not killed by this exposure. Boiling, i.e., exposure to 100° C., suffices to kill all vegetative forms of bacteria within a few minutes, but sterilization is not effected, for the spores of many of the saprophytic bacilli are not destroyed by boiling for many hours. Since very few of the pathogenic bacteria form spores, boiling contaminated water for a few minutes renders it safe for drinking purposes, and the boiling of surgical instruments generally suffices to kill the vegetative cells of pathogenic bacteria, but not the spores of spore-forming pathogens such as those of the tetanus and gaseous gangrene bacilli.

Temperatures as high as 100° C. are not necessary for the destruction of vegetative forms of bacteria, since most of them are killed at 55° to 58° C. if exposed for 10 to 30 minutes. A vacuum-steam method of

disinfection, especially applicable to textile products such as blankets and clothing, has been described² in which the autoclave is evacuated to 20 mm. Hg and steam run in to the desired temperature. A temperature of 70° C. for 12 minutes killed vegetative cells, but a higher temperature, 105° C., was required to kill anthrax spores. In the preparation of vaccines, suspensions of bacteria are usually heated to 60° C. for 30 minutes to one hour (to allow an adequate margin of safety). The tubercle bacillus, Brucella abortus, and other pathogenic organisms occurring in milk are killed by the process of pasteurization, i.e., heating to 142° to 145° F. for 30 minutes.

Dry heat is much less effective as a germicide than moist heat. Temperatures of 160° to 170° C. must be maintained for two to three hours in order to ensure complete destruction.

Sterilization by heating is a common and useful procedure, and the nature of the material to be sterilized determines whether moist heat or dry heat is used. Bacteriological mediums, solutions, etc., are sterilized by steam under pressure in an autoclave, provided that the contained substances are heat-stable, while laboratory glassware, syringes, hypodermic needles, etc., are usually sterilized by dry heat in a thermostatically controlled oven (see Chap. Two). The temperature is ordinarily kept constant, 120° C. and 170° C. respectively, but the time required for sterilization depends upon the volume of liquid, how closely the containers are packed, and similar factors that affect penetration of heat to effective sterilizing temperatures.

The destructive effect of high temperatures on bacteria is apparently associated with the coagulation of constituent protein. The rate of heat coagulation of protein in solution closely parallels the rate of destruction of bacteria by hot water. Furthermore, the effect of the water content of egg albumin on the temperatures necessary for coagulation is similar to the observed relative efficiency of moist and dry heat in the killing of bacteria.*

^{*}Egg albumin in aqueous solution is coagulated at 56° C.; with 25 per cent water content at 74° to 80° C.; with 18 per cent water content at 80° to 90° C.; with 6 per cent water content at 145° C. Anhydrous egg albumin may be heated to 170° C. without coagulation,

COLD 181

Cold. In general, cold has a preservative effect on microorganisms in that, as the temperature is lowered from the optima for growth processes and other physiological activities, the metabolic rate is reduced. The temperature coefficient is substantially the same as that of other living organisms, i.e., the metabolic rate is reduced by approximately half for each 10° C. drop in temperature over the relatively narrow range in which the effect is demonstrable. Thus, microorganisms grow and metabolize rapidly at incubator temperatures, but tend to persist in a semidormant state at usual refrigerator temperatures (2° to 8° C.), and storage in the refrigerator is a common method of preserving bacterial cultures over a limited time.

The effect of chilling is not invariably preservative. Some microorganisms, such as the influenza virus, are still inactivated sufficiently rapidly at refrigerator temperatures that they may be preserved for only a few hours. Still other microorganisms, notably the gonococcus and meningococcus, tend to die out even more rapidly at refrigerator than at incubator temperatures.

Extreme low temperatures. It is commonly said that microorganisms survive freezing and extremely low temperatures such as those of liquid air (-190° C.) and liquid hydrogen (-250° C.). The effect of exposure to, and storage at, temperatures below the freezing point of water is undoubtedly injurious to a greater or lesser extent, but when some, even relatively few, of the millions of individual cells present are found to be viable, the microorganism is said to "survive" the treatment. Many, perhaps very many, are killed as a consequence of the operation of lethal factors, and the significant variables are the rate of freezing, the temperature at which the frozen cells are stored, and the rate at which they are thawed.64

When the cells are frozen slowly there is a preferential formation of extracellular crystal nuclei, and their growth produces an increase in extracellular osmotic pressure, withdrawing water from the cell which is added to the growing crystals. The freezing point of the remaining water is depressed by the increasing concentration of soluble substances as the temperature is reduced; the unfrozen water decreases from as much as 50 per cent of the total at the freezing point to less than 10 per cent at -10° C.

When the freezing is extremely rapid, the tendency to extracellular crystallization diminishes and intracellular crystallization occurs. In the first instance two lethal effects are operative, the one that of high electrolyte concentration and the other dehydratior denaturation. Very rapid freezing minimizes the first effect, but not the second.

The lethal effects are time and temperature dependent, declining exponentially with reduction in temperature and extrapolating to zero at the glassy transformation temperature (-130° C). There is a third potentially lethal factor affecting material that has been frozen sufficiently rapidly to give intracellular ice crystals; that of growth of the intracellular crystals, which is also directly and exponentially related to temperature. The lethal effects of these factors are also species-dependent in that some kinds of microorganisms are less affected by them than others.

In practice, storage at a temperature of -50° C. or less is required for prolonged viability. For example, the cholera vibrio, one of the more delicate bacteria in this respect, dies off within a few hours when stored as a frozen suspension at -25° to -30° C., but remains viable for at least two years at -65° C. So the ordinary "deep freeze" is not cold enough for storage of frozen bacterial cultures, but a dry-ice refrigerator, or its equivalent, is.

The sequence of events occurring in the course of freezing is reversed in the thawing process, with the rates of denaturation and crystal growth increasing exponentially as the temperature rises. The process is, in fact, more rigorous than that of freezing because of the kinetics of heat exchange, and rapid thawing is required to minimize lethal effects. It is obvious that the effects of these three phases of the process—freezing, storage, and thawing—cannot be separated from one another but may be evaluated only relatively when two are held constant and the third varied.

Drying. The vegetative forms of most bacteria are killed by drying in air, although the different species exhibit pronounced differences in their resistance. The tubercle bacillus is one of the more resistant and the cholera vibrio one of the more sensitive to drying. In general, the capsulated organisms are more resistant than the noncapsulated forms. Spores are quite resistant to drying;

the spores of the anthrax bacillus, for example, will germinate after remaining in a dry condition for 10 years or more. The resistance of the pathogenic forms causing disease of the upper respiratory tract is of particular interest in connection with airborne infection, for the length of time a droplet remains infective is a function, primarily, of the resistance of the particular microorganism to drying.29 The observed lethal effect of suspension of microorganisms in air is largely a function of relative humidity, and it has been found that maximal death occurs at about 50 per cent relative humidity. This is apparently a consequence of the amount of water retained in the droplets; at very low humidities the rapid desiccation renders the organism resistant to the toxic action of soluble substances concentrated by the partial drying, while at high humidities sufficient moisture is retained to keep such substances from reaching toxic concentrations.

Freeze-drying. 35, 101 The resistance of a given organism to drying is apparently determined to some extent by the rapidity of the drying process and the temperature at which the organisms are dried and stored. If bacteria are frozen rapidly, as with dry ice and alcohol or one of the glycols, dried from the frozen state (the lyophile process). and the container or ampoule evacuated and sealed, they remain viable with antigenicity and virulence unimpaired for months and years when stored in the refrigerator. It has been calculated, by extrapolation, that the survival time ranges from decades for vibrios and Acetobacter to centuries for staphylococci under these conditions.32 Most of the bacteria are killed in the process, with less than 1 per cent surviving,25 and it is these few survivors that grow on subculture. Probably the most important single factor in survival is the menstruum in which the bacteria are suspended. Poor results are usually obtained with ordinary broths, and the addition of normal serum, lactose, and other ingredients contributes to survival.31 Survival has been of particular interest in the preparation of BCG vaccine in a stable dry form; the inclusion of sodium glutamate apparently contributes considerably to the survival of this microorganism (Chap. Thirty-one).36, 81

Radiation.^{58, 59, 72, 102} There is little biological effect of visible light on non-chloro-

phyll-containing microorganisms except in the presence of certain dyes which increase absorption of light, and energy, to produce inactivation. This appears to be due in large part to the formation of peroxides and is inhibited in the presence of catalase. The phenomenon is called photodynamic sensitization.

Beginning in the ultraviolet region, the biological effects of radiation become pronounced, and the well-known bactericidal activity of direct sunlight is due to its content of ultraviolet light. The effects of ionizing radiation, x-rays and γ -rays (short x-rays) being the most commonly used, are even more marked.

With relatively large doses of radiation the microorganism is inactivated in that it will no longer reproduce, or, in the case of pathogens, produce infection, although overt evidences of viability such as respiration rate are not affected appreciably. With smaller doses, not sufficient to inactivate, the genetic mechanisms of irradiated microorganisms become unstable, and the mutation rate is increased from the normal spontaneous rate of perhaps 10⁻⁸ to as much as 10⁻³. Similar doses applied to lysogenic bacteria activate the latent infection with provirus so that complete virus is produced and the host cells are lysed as described elsewhere (Chap. Four).

Both ultraviolet and ionizing radiations are electromagnetic waves emitted in quanta, but they differ in the way in which biological effects are produced because they are absorbed differently, and because their quanta carry greatly different amounts of energy.

Ultraviolet radiation. Absorption in the region between 2500 and 3000 Å is due in part to the aromatic amino acids and cystine, with the peak at 2800 Å attributable to tryptophan and tyrosine. The peak absorption by nucleic acids, i.e., the purine and pyrimidine rings, occurs at around 2600 Å. Nucleic acids absorb much more strongly than proteins, and 25 to 50 times more energy is absorbed per unit weight by the former than by the latter. It is more than coincidence that the region of maximal absorption in the ultraviolet is also that of maximal antimicrobial activity.

At 2537 Å, the most effective and commonly used wave length, a quantum of ultraviolet radiation has an energy of about 5 ev. This is not sufficient to eject an elec-

RADIATION 183

tron to form an ion, a process which requires an average of 30 ev in biological material. but is enough to raise a constituent electron to a higher state of energy and thus produce excitation rather than ionization. Modification of molecules occurs by the breaking of bonds (for example, a covalent bond may be broken by about 4 ev), but since such events occur at random in the sense that they do not necessarily affect essential functional mechanisms, the effects of ultraviolet radiation are less than those of ionizing radiation. The surrounding medium is affected also, and the formation of peroxides contributes to the antimicrobial effects of irradiation. In total, about 100 times as much energy is required to inactivate microorganisms by ultraviolet radiation as by xradiation, and it is calculated that about 4 million quanta are necessary to inactivate a colon bacillus.

The effects of ultraviolet radiation are not completely established immediately, and for some time, even as much as several hours, they may be modified by exposure of the microorganisms to visible light. This phenomenon is that of photoreactivation.¹⁸ The mechanisms involved are far from clear, and two kinds of hypotheses are current. The exposure to visible light may, in some obscure way, repair damage caused by the inactivating radiation, or it may provide a possible alternative mechanism to replace that which was damaged. Reactivation may also occur following short exposure to heat (45° C.) or the addition of substances such as catalase, peroxidase, or some organic substances.

Ionizing radiation. Ionizing radiation includes α -rays (nuclei of helium atoms), β -rays (fast-moving electrons), γ -rays, and x-rays. As ionizing radiation passes through a microorganism, it collides with successive atoms to eject electrons and so create columnar zones of intense ionization. Secondary ionization, produced by ejected electrons along different paths (δ -radiation) may be of quantitative significance, especially with α -radiation.

The resistance of microorganisms, both bacteria and viruses, is relatively high, 10⁶ rads* or more being required for 99 per cent

inactivation. There is reason to believe that radiation effects may be a consequence of a direct hit of key substances within the cell, and their destruction or alteration by the intense ionization. This is the target theory, but it is not fully consistent with radiation protection.⁴⁶

The effects of radiation are modified in various ways. The oxygen effect, *i.e.*, the reduced radiosensitivity of a microorganism when oxygen is displaced with an inert gas or removed by metabolism, is well known. Similarly, certain compounds, especially those containing sulfhydryl groups, give excellent protection against radiation damage.

Radiation damage. The effects produced are basically biochemical in nature and appear to revolve to a considerable extent about injury to the genetic mechanisms, including the blocking of DNA synthesis. Other synthetic reactions, notably the formation of adaptive enzymes (Chap. Seven), are inhibited also. The processes of cell division appear to be affected more readily than at least some synthetic processes, and inactivated rod-shaped bacteria, for example, continue to grow for a time in filamentous form but do not reproduce. The marked increase in mutation rate resulting from irradiation in doses less than those required for inactivation has been taken to suggest that inactivating doses may give rise to lethal mutations which prevent subsequent multiplication of the irradiated cells.

Radiation-pasteurization. 7, 68 Inactivation of microorganisms by irradiation has some practical application in the preparation of vaccines and possibly also in the preservation of food. There is some reason to believe that vaccines prepared by radiation-inactivation of pathogenic microorganisms, such as dysentery bacilli and poliovirus, are superior immunizing agents because this kind of inactivation produces less change in significant antigenic substances than treatment with heat or disinfectants such as formaldehyde. Ultraviolet radiation has been used for this purpose but, because its lack of penetration poses some technical problems in the application of uniformly inactivating but not excessive doses, has not been widely used.

The application of irradiation to the preservation of foods has been of considerable interest. Radiation having high penetration is required, and of the several types, x-ray

^{*}A rad is defined as the amount of radiation required for the absorption of 100 ergs of energy per gram of substance having unit density.

and y-ray have practical applicability in this respect. X-rays may be generated in the conventional ways, and Co⁶⁰ can be used as a source of γ -radiation. The spores of Clostridium botulinum, routinely used for evaluating many food preservation procedures, are relatively resistant to radiation, and it has been found, for example, that 106 to 10⁷ rads is required for the destruction of the spores in meat to the acceptable standard of efficacy.55 While there is no residual radioactivity of any consequence, undesirable flavors are often produced which can be only partially eliminated by devices such as the incorporation of acceptable free radical acceptors. At lower dosages partial destruction is achieved which may have some utility in supplementing other procedures such as refrigeration.

Electrophoresis. Microorganisms are apparently unaffected by the passage of electric currents through their suspensions, provided that the effects of heating and acidity and alkalinity in the vicinity of the electrodes are controlled. They do, however, carry a charge that is a composite of those of the amphoteric substances comprising them, and at neutrality they are negatively charged, with an iso-electric point at pH 3 to 4. At alkalinities above the iso-electric point they move in the electric field toward the cathode, and this is known in the older literature as cataphoresis rather than electrophoresis. Bacteria are too large to move freely in a supporting medium such as paper, but certain of the viruses are separable by paper electrophoresis.

Cell disintegration. The bacterial cell may be broken up by physical means in a number of ways. The cells may, for example, be dried, commonly with acetone, or frozen,

and ground with alumina. The cell structure may also be broken down by the grinding action developed in shaking vigorously with small glass beads or similar particles. This is the principle of the Mickle disintegrator which shakes a mixture of bacteria suspension and small glass beads rapidly at the ends of a tuning fork. Or bacteria may be broken up by subjecting them to sudden changes in pressures of the order of 500 to 600 atmospheres, by sudden application or release of the pressure,24 but they are killed without disruption by the application of very high pressures, such as 10,000 atmospheres, which also denature proteins. Methods such as these split the cell wall, allowing the constituents of the cell to escape, and are used for the preparation of cell walls as well as for the study of intracellular enzyme activity, etc.

Still another method of breaking up the cell is treatment with sonic or ultrasonic vibrations. Sonic vibration at 9 to 10 kc. breaks up fragile bacteria, such as the cholera vibrio, in a few minutes, but others, such as lactobacilli, require longer treatment. Ultrasonic vibration at 30 to 100 kc. with reasonably large power input, perhaps 400 w., breaks up the cells much more rapidly. In either case there is a marked tendency to fragment the cell wall also, and some degree of denaturation of enzymatic activity often occurs.

Such physical destruction of the bacterial cell is, of course, lethal in that the fragmented cells are killed, and viable cells are rapidly reduced in number, but complete sterilization is extremely difficult to attain by such methods. There seems to be as yet no generally accepted theoretical basis for the effects of ultrasound.³⁹

Disinfectants 71, 78, 99, 102

Many kinds of substances have a deleterious effect on microorganisms. Antimicrobial substances have two kinds of activity, the one bactericidal, germicidal, or virucidal, and concerned with the killing of microorganisms, and the other bacteriostatic or growth-inhibiting. The line of demarcation between the two kinds of effects is not a sharp one, in that a bactericidal substance may inhibit growth rather than kill in low concentrations or when the period

of exposure is limited. It is quite generally observed also that concentrations just below those at which an antimicrobial effect becomes apparent markedly stimulate bacterial growth.

In a general way, a substance is regarded as primarily bacteriostatic when the range of concentration over which inhibition of growth occurs is a relatively wide one, and primarily bactericidal when it is narrow. Similarly, when the rate of killing is slow,

the exposed microorganisms may survive, in diminishing numbers for a considerable time without growth, and, for these survivors, the antimicrobial activity is growth-inhibiting. Conversely, when the rate of killing is rapid, and survivors are detectable for only a short time, the activity is regarded as primarily lethal. The distinction between lethal and growth-inhibiting activity is, therefore, two-fold in that it is dependent upon both concentration and rate effects and upon their interrelationship. So the distinction is one of degree rather than kind and is clear only at extremes.

The terms antiseptic and disinfectant are applied to describe antimicrobial activity. Etymologically, both imply the effective removal of pathogenic microorganisms, but by usage they have come to have somewhat different meanings. An antiseptic is a substance that has sufficient antimicrobial activity to interfere with the development of infection, but which is nontoxic when applied superficially to living tissue. A disinfectant is a more potent substance of marked antimicrobial activity which destroys all, or nearly all, pathogenic microorganisms but, because of associated toxicity, is applicable only to inanimate material. In each case the terms must be defined with respect to the microorganism against which the substance is tested or expected to be used, for a given substance may be an effective disinfectant for one kind of microorganism but not another. The term disinfection is also broadened to cover the process of destruction of pathogenic bacteria by either chemical or physical means.

Antimicrobial activity is a property of a wide variety of substances, both inorganic and organic in nature, and the exploitation of combinations of antimicrobial activity and toxicity and/or corrosive properties is a matter of considerable practical importance. Those having sufficiently low toxicity to allow them to be injected parenterally into the diseased host to reach and maintain effective antimicrobial concentrations in the tissues are the chemotherapeutic drugs, and are discussed in the following section; those that are useful as disinfectants and antiseptics are considered here.

Inorganic compounds. A number of inorganic substances have antimicrobial activity because of the toxicity to microorganisms of ions into which they disso-

ciate, or because of their activity as oxidizing agents to bring about some degree of cold combustion of cell substance.

Acids and alkalis. Both strong acids and strong alkalis, i.e., those that are highly dissociated, exert a marked bactericidal effect. The lethal activity of the mineral acids is associated with, and proportional to, the degree of their dissociation, but that of the organic acids appears to be an effect of the whole molecule, for the degree of dissociation is, as a rule, not great. The disinfectant action of alkalis such as sodium hydroxide is likewise proportional to the degree of dissociation. The germicidal activity of the hydroxides of the alkaline earths is, however, greater than can be accounted for on the basis of dissociation, for the metallic ion is often toxic in itself. Both acids and alkalis, in too low a concentration to kill bacteria rapidly, often enhance the activity of other disinfecting agents. For example, the germicidal activity of many salts is greater in the presence of acid or alkali, and, as noted above, bacteria are killed much more rapidly by heat in the presence of dilute acid or alkali than at neu-

The relation of bacterial growth to the acidity or alkalinity of culture mediums has been discussed elsewhere. Concentrations of hydrogen or hydroxyl ions compatible with growth are very low, of the order of 10⁻⁴ to 10⁻⁹ mols of hydrogen ions per liter. Almost all bacteria will grow at pH 7.0 $(1 \times 10^{-7} \text{ mols hydrogen ions per liter})$ but grow best at an optimum which varies from species to species. The minimum and maximum limits between which growth takes place likewise vary widely with species. Certain organisms such as the lactobacilli and Streptococcus lactis are termed aciduric organisms because they are able to grow profusely at pH 4.0 or less. Perhaps the most acid-resistant organism known is Thiobacillus thiooxidans. This organism accumulates sulfate in its cultures as an end product of the oxidation of sulfur and continues to grow even in the presence of N/10 sulfuric acid (Chap. Five).

Salts. Salts have, in general, two effects on bacteria. In very low concentrations they markedly stimulate growth and at higher concentrations they become toxic. The particular concentrations at which these effects are apparent are dependent upon the degree of dissociation of the salt, the

nature of the anion and the valency and molecular weight of the metallic ion. In general, the bivalent cations are more toxic than the monovalent cations, and the salts of the heavier metals are more toxic than those of the lighter metals. There is, however, no precise quantitative relation in either case.

The most active of the heavy metals are mercury, silver, and copper. Mercuric chloride is highly active in 0.1 per cent aqueous solution but the activity is bacteriostatic in a sense in that the treated cells may be "revived" by removal of the mercuric ion with hydrogen sulfide. In general, relatively few mercury compounds have antibacterial activity, and those which do as a result of the presence of mercuric ion are primarily bacteriostatic rather than bactericidal. The silver salts, such as silver nitrate, although somewhat less active, are still highly efficient germicides. Copper salts are still less active but are highly efficient in the destruction of algae and other chlorophyll-containing organisms. Dissociation of these salts is intimately related to their disinfectant properties. A solution of mercuric chloride in absolute alcohol has substantially no antibacterial activity, but if water is added the activity of the solution increases in proportion to the amount of water added. Because of the importance of ionization, a comparison of the bactericidal power of the various metallic salts on the basis of percentage solution is misleading; equimolecular solutions must be used and the ionization constants taken into consideration. The antimicrobial activity of the heavy metal salts is a result of the affinity of the cations for protein material; when the constituent protein of a bacterial cell is precipitated as an insoluble proteinate, the cell dies. Other factors appear to be involved also, however. It has been observed that inorganic metallic salts which are only slightly bactericidal individually may become markedly active when mixed to produce an oxidation-reduction system.

The oligodynamic action of metals is possibly a result of the solution of the metal to form salts. The destruction of bacteria in contact with or in proximity to a piece of metal is the basis of some methods of disinfection of water. Water may be sterilized by allowing it to seep through a layer of silver-coated sand, and water containing colloidal silver in amounts sufficiently small to defy chemical detection, by calculation

about 40 γ per ml., is markedly bactericidal. Such colloidal solutions are prepared by sputtering silver electrodes in water—the so-called catadyn process.

The other cations are less toxic than mercury and silver, but even sodium and potassium are toxic to bacteria in sufficiently high concentrations (ca. 2 molar). It is of some interest that the arrangement of cations in an order of their toxicity-mercury and silver at one end and sodium and potassium at the other, with others falling in order in between-corresponds closely to the Hofmeister series and the lyotropic series of Freundlich, in which cations are arranged in the order of their effects on physical properties of proteins, such as coagulation, solubility, and viscosity. The toxicity of cations as manifested in solutions containing a single salt may often be neutralized by the presence, in the proper proportion, of another cation. This phenomenon, known as the antagonistic effect of salts, has led to the concept and preparation of so-called balanced solutions such as Ringer's solution and Locke's solution. Salts not only modify or enhance the toxic qualities of other salts but also exert similar effects on disinfectant compounds of widely different constitution. Sodium chloride, for example, markedly enhances the germicidal qualities of phenol for anthrax spores when present in sufficiently high concentrations.

The part which anions play in the growth and destruction of bacteria is less well known. Some, particularly those containing sulfur, carbon, nitrogen, or oxygen, may serve as sources of these elements and of energy, but in appropriate concentrations many are toxic for bacteria.

Oxidizing agents. Other salts, such as potassium permanganate and the sodium and calcium salts of hypochlorous acid (HOCl), show marked bactericidal activity owing to their properties as oxidizing agents. Mol for mol, hypochlorous acid is one of the most powerful germicides known, and its calcium salt (commonly known as bleaching power) has a wide use in the treatment of private and small municipal water supplies. Hypochlorous acid reacts with organic compounds containing an amide group with the formation of compounds known as chloramines. These compounds show strong disinfectant properties which are apparently associated with the presence of the =NCl group. Two of these, chloramine-T and PHENOLS 187

dichloramine-T, were used with considerable success in the disinfection of deep wounds in World War I. Similar compounds such as the chlorates and perchlorates likewise are bactericidal. The high bactericidal activity of chlorine dioxide has been of considerable interest in connection with its use in the treatment of water supplies, since it is relatively unaffected by alkalinity but, unlike hypochlorite and chlorine, its residuals, largely organic chlorine compounds, are relatively inactive.8 The halogens, chlorine, bromine, and iodine, are also potent germicides but, in contrast to the heavy metals, in inverse order to their atomic weights. Liquid chlorine is widely used in the treatment of water supplies, and iodine in the form of its tincture is an efficient skin disinfectant. Bromine has been used occasionally as a disinfectant for swimming pool water.62 Fluorine compounds are seldom used as disinfectants, although sodium fluoride is toxic to some bacteria, presumably owing to its interference with their oxidative mechanisms. Both hydrogen peroxide and ozone are bactericidal, but the former is rapidly decomposed by tissue catalase and has little penetrating power when applied to wounds and abrasions.

Organic compounds. A variety of organic compounds have antimicrobial activity and are useful as antiseptics and disinfectants. The more important are certain metal-organic compounds, phenols and related compounds, soaps and alkyl sulfate detergents, quaternary ammonium compounds, and a few alcohols and ethers.

Metal-organic compounds. More or less successful attempts have been made to utilize the germicidal activity of mercury and silver through the preparation of organic compounds which, while having disinfectant properties, are not markedly toxic to body tissue. These include Metaphen, Merthiolate, Mercurochrome (dibrom-oxymercurifluorescein), Mercarbolide, Merphenyl nitrate, Mertoxol (acetoxymercuri-2-ethylhexyl-phenolsulfonic acid), and Meroxyl

(sodium salt of 2-4-dihydroxymercury benzophenone-2'-sulfonic acid), together with a series of silver-protein compounds such as Argyrol, Protargol, Argonin, and the like (1). The organic compounds of mercury are generally used as skin disinfectants, though they are of doubtful value, and, in dilute solution, as preservatives. Merthiolate, for example, in 1:10,000 concentration is an excellent and widely accepted preservative for antiserums and similar biologicals. The silver compounds have utility in the treatment of infections of the mucous membranes.

Phenols. Phenol and its derivatives are among the most useful of the antibacterial organic compounds. Phenol itself destroys the vegetative cells of bacteria rapidly, and spores more slowly, in 5 per cent aqueous solution, and its activity is not seriously reduced in the presence of organic matter. It is used as the standard of comparison for other disinfectants, particularly those of similar chemical structure.

The activity of phenol is enhanced by substitution in the ring. The methyl phenols, ortho, meta, and para cresols, and halogenated phenols have greater activity than the parent compound. Resorcinol, hydroxyphenol, however, is only mildly bactericidal. In general, the substitution of aliphatic side chains in both phenol and hydroxyphenol increases antibacterial activity in direct proportion to the length of the side chain, but solubility in water is decreased to limit the practical value of such compounds.⁹

The bisphenols have become the most useful of the phenolic disinfectants because of their relatively high bacteriostatic and fungistatic properties and relatively low toxicity. As indicated by the name, these compounds consist of two phenol rings attached carbon-to-carbon or through oxygen, sulfur, or alkalene, especially methylene, groups. The position of the linkage with respect to the phenolic hydroxyl group is an important factor, and the nomenclature of these compounds becomes involved be-

1.

Mercarbolide

cause the carbon numbered 1 may be that to which the hydroxyl group is attached or that at which the linkage occurs. When the compound is symmetrical either may be used, but only the latter nomenclature may be used when it is asymmetrical.

The most important of these compounds are orthohydroxydiphenyl and the chlorinated methylene and sulfur compounds. Orthohydroxydiphenyl is marketed as O'Syl and Lysol, the latter containing cresylic acid also. There are three common chlorophenes. The simplest is dichlorophene (G-4) in which the methylene linkage is ortho to the hydroxy groups and the chlorines in the para positions. Depending upon the system of nomenclature this compound is 2,2'-methylenebis[4-chlorophenol], chloro-2-hydroxyphenyl]methane, or 2,2'dihydroxy-5,5'dichlorophenylmethane. The other two are tetrachlorophene (G-5) containing two additional chlorines, one on each ring ortho to the hydroxyl group, and hexachlorophene (G-11). The thio bisphenols in common use are bithionol (G-5-S), which corresponds to tetrachlorophene in that it contains four chlorines, and G-11-S, which corresponds to hexachlorophene (2). Hexachlorophene has the unusual and useful property of retaining substantially all its antibacterial activity when incorporated into soaps. These compounds are relatively insoluble in water, but are soluble in dilute alkali and in many organic solvents.

These compounds differ from phenol in their activity in that, while they are somewhat more active than phenol under the conditions of the phenol coefficient test (see below), more prolonged exposure is required for maximal bactericidal activity, and they are bacteriostatic in high dilutions. Dichlorophene, for example, gives phenol coefficients of 20 to 40 against staphylococcus and 50 to 75 against the typhoid bacillus, and hexachlorophene 25 to 50 against the former test organism and 5 to 10 against the latter. Dichlorophene, however, inhibits the growth of staphylococcus in dilutions of 1:500,000, and hexachlorophene in dilutions as high as 1:2,500,000.

Detergents. The surface-active detergent substances fall into three groups (3). The anionic compounds are soaps, sodium and potassium salts of higher fatty acids, and the alkyl sulfates such as sodium lauryl sulfate. The quaternary ammonium compounds are cationic substances, and the nonionic group includes polyethers and polyglycerol esters. Certain of these substances have antibacterial activity.

The antimicrobial activity of soaps is limited, and they cannot be regarded as

Surface-active (detergent) substances

DETERGENTS 189

effective antiseptics or disinfectants. They are useful agents for the mechanical removal of bacteria from the skin by emulsification of lipoidal secretions in which microorganisms are embedded. Thus the number of bacteria present on the skin is markedly, but temporarily, reduced by washing with soap. An appreciable antibacterial activity may be given soaps by combining them with disinfectant substances, commonly coal tar products such as cresols and related compounds, but, in general, the activity of the incorporated substance is reduced in admixture with soap. Hexachlorophene is, as noted above, a significant exception to this general rule. The use of hexachlorophenecontaining soaps results not only in an immediate reduction of the numbers of bacteria present on the skin, but the bacteriostatic activity of the residual hexachlorophene significantly inhibits the growth of bacteria on the skin.

Some of the alkyl sulfates have more antibacterial activity than soaps, inhibiting growth in relatively high (0.1 per cent) concentrations. Those which are active are markedly selective, affecting gram-positive bacteria but not gram-negative bacteria.

The quaternary ammonium compounds, often called "quats," are a group of amines containing pentavalent nitrogen and may be regarded as derivatives of ammonium chloride in which various radicals are substituted for the hydrogens. Ordinarily one is a long-chain (C_8 to C_{18}) alkyl group,

and the others smaller alkyl groups, phenyl groups, etc. Very many, perhaps a thousand, of these compounds have been synthesized, and several, including Zephiran (alkyldimethylbenzylammonium chloride), Ceepryn (cetylpyridinium chloride), Phemerol (diisobutylphenoxyethoxyethyldimethylbenzyl ammonium chloride), and Diaparene (diisobutylcresoxyethoxyethyldimethylbenzyl ammonium chloride) have gained general acceptance (4).

These substances are equally effective against gram-positive and gram-negative bacteria. They vary somewhat in activity. Zephiran, for example, is bactericidal to staphylococcus in dilutions as high as about 1:40,000 and bacteriostatic in dilutions as high as 1:200,000. The phenol coefficient of this compound has been found to range from 150 to 300 at room temperature against both staphylococcus and the typhoid bacillus, but the applicability of the phenol coefficient method to the assay of the activity of compounds of this kind is open to question.

There is a marked incompatibility between anionic and cationic detergents in that in mixture the antibacterial activity disappears. The nonionic detergents do not have this effect and, for example, quaternary ammonium compounds may be mixed with nonionic detergents having good solubilizing activity to give an antibacterial cleansing agent.

Alcohol and ethers. Ethyl alcohol and ethyl ether, often used as skin disinfectants,

$$\begin{bmatrix} CH_3 \\ CH_3 \\ CH_3 \\ CH_3 \end{bmatrix} CC$$

are not very good germicides. Their effectiveness probably lies in the solution of the lipoidal secretions of the skin and consequent mechanical removal of microorganisms. Absolute alcohol has little or no germicidal activity. The bactericidal activity of alcohol-water solutions increases with the addition of water, but 50 per cent alcohol and less has little activity; 70 per cent is the concentration usually used for skin disinfection. Absolute propyl and isopropyl alcohols are likewise ineffective but show activity in aqueous solution, while absolute methyl alcohol is said to be bactericidal.

Gaseous disinfectants. 11, 40 The use of bactericidal gases for the disinfection of rooms, dwellings, and the like (fumigation or terminal disinfection) has declined markedly in recent years with no coincident increase in the prevalence of infectious disease. The commonly used gas, sulfur dioxide (generated by burning flowers of sulfur), is probably not bactericidal as a gas but is bactericidal in aqueous solution; it is effective, therefore, only in the presence of adequate amounts of moisture (a relative humidity of 60 per cent or higher). Other gases such as hydrogen cyanide have little or no effect on bacteria. Although the value of terminal disinfection is open to serious question, that of disinfestation is well established and the gases, hydrocyanic acid in particular, are widely used for the destruction of rats aboard ship, and like purposes.

Alkylating agents. Certain of these have been found to be highly effective bactericides in gaseous form, both on solid objects and solutions, and on bacteria suspended in air. These include ethylene oxide, propylene oxide, ethylene amine, methyl bromide, and formaldehyde. These substances have the unusual property of being relatively more effective in the destruction of bacterial spores than the usual disinfectants, and their activity seems to be irreversible and bactericidal.

Formaldehyde has been used for many years, but is often unsatisfactory because it penetrates poorly and requires a relatively high humidity. It has been used more recently in combination with low temperature steam-vacuum sterilization for textiles and similar materials.³

Ethylene oxide is a more recent development and is similarly highly effective. It forms an explosive mixture with air, but the attendant danger is prevented by mixing with 7 to 10 volumes of carbon dioxide; the mixture is commonly called *carboxide*. It may be applied to fabrics or equipment of various kinds under pressure; the objects to be sterilized are treated in the dressing sterilizer type of autoclave which is evacuated to 14 pounds, and ethylene oxide run in to 20 to 23 pounds pressure and left overnight. Relative humidity is an important factor,²⁷ and it has been reported that ethylene oxide is more effective at higher temperatures.¹⁹

It is of some interest too that culture mediums can be so sterilized, with apparently no residual antibacterial activity remaining. This method of sterilization is particularly applicable to plastic disposable petri dishes and test tubes which cannot be sterilized by the conventional heating methods.

Another alkylating agent which has been of particular interest is β-propiolactone. 15, 38 Unlike ethylene oxide, it is not inflammable, but requires a high humidity (80 per cent) to be effective, and has only limited penetrating power so that it functions most effectively as a surface disinfectant. It is highly bactericidal and virucidal in concentrations of 1 to 5 mg. per liter and is considered to be about 25 times more effective than formaldehyde. While lacking the general utility of ethylene oxide, it is especially effective in the decontamination of enclosed spaces such as rooms and buildings. 12, 90 and may also be used for the sterilization of heat-labile materials.34 It is viewed with reservation by some because it has been found to be carcinogenic in the mouse.

Aerosols. An aerosol may be defined as a finely dispersed substance in air, and aerosols are of interest in connection with the destruction of air-borne microorganisms. Suitable substances must not only have antimicrobial activity, but also be sufficiently nontoxic and nonirritating that they may be inhaled by man and other animals for reasonable periods. The most commonly used compounds are glycols, especially triethylene glycol.

The glycol is relatively nontoxic and the vapor may be breathed with impunity, but bactericidal concentrations of 50 per cent or higher are attained in contact with suspended microorganisms. The rate of destruction of air-borne bacteria is in agreement with the assumption that the glycol mole-

cules in the vapor state condense on the bacteria-containing droplets, and efficacy is associated with a low vapor pressure, high hygroscopicity, and, of course, toxicity for the bacterial cell substance.^{57, 74, 75}

While pathogenic microorganisms such as pneumococcus, streptococcus, and influenza virus are killed or inactivated rapidly under experimental conditions, in general aerosols have given disappointing results when used for practical control of air-borne infection.

Dyes. The dyes are widely used in bacteriology both for staining purposes and as indicators. In addition, many of them show a marked bacteriostatic and bactericidal activity which is often specific in that it is manifested against one organism and not another. The incorporation of an appropriate dye in a medium will render it selective; i.e., it will favor the growth of some species of bacteria and inhibit that of others. In general, this specificity is correlated with the Gram reaction; the gram-negative organisms are, for the most part, much less sensitive to dyes than are the gram-positive species. The activity of these compounds is affected by pH, the toxicity of the acid dyes increasing with acidity and that of the basic dyes increasing with alkalinity.

Many of the dyes such as the thiazins, oxazins, and azo dyes are not particularly toxic for bacteria, dilutions of 1:1000 or less being required to inhibit growth. A number of the triphenyl methane dves are. on the other hand, inhibitory in high dilutions. Malachite green, for example, inhibits the growth of B. subtilis in dilutions 1:4,000,000 and staphylococci in 1:1,000,000, while higher concentrations, i.e., 1:30,000 to 1:40,000, are required to inhibit the colon and typhoid bacilli. Victoria green, a dichlor derivative of malachite green, is bacteriostatic to about the same degree. Brilliant green is active in even higher dilutions, inhibiting B. subtilis in a dilution of 1:15,000,000 and staphylococci in 1:4,000,000, and the typhoid and colon bacilli in 1:500,000.

The bacteriostatic properties of the triamino-triphenyl methane dyes, the so-called rosanilins, are apparently associated with the substitution of alkyl groups in the amido side chains. Basic fuchsin, a mixture of the unsubstituted simple dyes rosanilin and pararosanilin, is relatively weakly bacteriostatic, dilutions of 1:500,000 being required

to inhibit the growth of B. subtilis. Acid fuchsin, a mixture of various sulfonated derivatives of basic fuchsin, is likewise only weakly inhibitory and was formerly widely used in mediums as an acid indicator under the name of Andrade's indicator. On the other hand, methyl violet* a mixture of tetra-, penta-, and hexamethyl pararosanilin, is markedly bacteriostatic and completely inhibits the growth of bacteria such as staphylococci and diphtheria bacilli in dilutions of 1:1,000,000 to 1:5,000,000. Approximately 150 times as much dye is necessary to suppress growth of the less sensitive gram-negative bacteria such as the colon and typhoid bacilli. There appears to be a correlation of bactericidal activity and basicity of these compounds.

The acridine dyes, acriflavine and trypaflavine, have been of particular interest because of their therapeutic significance. The former is actively bacteriostatic in dilutions as high as 1:3,000,000, and the latter inhibitive to staphylococci and similar organisms in 1:2,000,000 and to the relatively fragile gonococcus in dilutions of 1:10,000,000 to 1:50,000,000. The gonococcus is killed by exposure to the dye in dilutions of 1:80,000 to 1:400,000 within two or three minutes.

The mechanisms of bactericidal action. The ways in which antimicrobial substances affect the cell so as to produce changes in its organization resulting in growth inhibition or death are varied and, as might be expected, dissimilar effects on the cell give the same end result. A substance showing bactericidal properties produces its effects through an interruption of essential physiological processes of the bacterial cell. In some instances the effect is relatively nonspecific, as in the denaturation of constituent protein, and in others highly specific in that some particular metabolic reaction is affected. There is some tendency to differentiate the former as a general protoplasmic poisoning, but this is more a matter of convenience than an expression of fundamental difference. A continuous series of degrees of specificity, so to speak, may be set up through which the general toxic effects grade imperceptibly into the inhibition of a single enzyme system.

^{*}Gentian violet is a more or less impure mixture of methyl violet and dextrin. Crystal violet, hexamethyl-p-rosanilin, is one of the constituents of methyl violet.

Thus, a general oxidation of cell substance by oxidizing agents, a saturation of thiol groups of constituent proteins with heavy metals, or a generalized denaturation of protein by, for example, substitution of halogens such as iodine in the ring structures of aromatic amino acids, obviously alters the organization of the cell on a macromolecular level to such an extent that normal metabolism cannot continue. Bactericidal substances of the phenol group apparently act in part in this way, in that phenol is surface-active and by orientation of the hydroxy group reacts with free amino groups of the cell proteins.

Or the effect may be somewhat more localized as in the case of the basic dves which react with nucleoprotein and whose action, at least that of acriflavine, is antagonized by nucleotides. Similarly, the surfaceactive detergents are antagonized by lipids. e.g., the anionic detergents by cephalin, and there is some reason to believe that they alter the permeability of the cell wall to such an extent that the cell dies. Phenols and other substances act similarly, and in general the antimicrobial effect of such agents is a net one, with leakage of cell contents due to permeability effects, possibly general protein denaturation, and adverse effects on the availability of coenzymes, activating ions, etc.

Generally speaking, the loss of enzyme activity is the most important single factor, 92 and even antimicrobial substances that appear to be general protoplasmic poisons often show a specificity of action. There is evidence that chlorine, for example, first affects a triosephosphate dehydrogenase Sulfhydryl-containing appear to be the most susceptible to the action of bactericidal substances, and poisoning by heavy metals, oxidizing agents, etc., occurs with some facility. The alkylating agents such as ethylene oxide act by direct alkylation, and the thiol group is probably the most vulnerable point in the cell organization. Azide markedly inhibits esterification of inorganic phosphate, and it has been suggested that it reacts with the acyl phosphate of diphosphoglycerate. The acyl azide is spontaneously decomposed and thus drains the energy-rich phosphate formed.

Often antimicrobial activity is paralleled by an inhibition of oxygen uptake, indicating a poisoning of the respiratory enzymes, and measurement of such inhibition has been suggested as a method of assaying bactericidal activity. This approach is not always valid, however, for some substances such as dinitrophenol stimulate oxygen uptake and prevent the assimilation of carbon; it inhibits assimilation by uncoupling phosphorylation and draining away the energy stored in energy-rich phosphate bonds. It will be clear that while information as to the precise point of attack of antimicrobial substances on cell organization and function is by no means complete, a variety of mechanisms are operative.

Reversal of antibacterial activity. croorganisms exposed to the action of a number of antimicrobial substances and apparently killed may be "revived" by neutralization of the activity within a short time after exposure. The revival of bacteria and viruses such as influenza virus, presumably dead after treatment with mercuric chloride, by treatment with hydrogen sulfide or thiols such as thioglycollic acid, glutathione, and the like is well established. Similarly, bacteria apparently killed with hypochlorite may be revived by inactivating the chlorine with sodium thiosulfate, and the use of thiosulfate solutions for dilution in titration of bactericidal activity of the hypochlorites to neutralize bacteriostatic concentrations carried over into subcultures is a common procedure. Bacteria treated with phenol survive if the phenol is removed by adsorption on charcoal or treatment with ferric chloride. The effects of treatment with dyes such as acriflavine or with cationic detergents may be neutralized with survival of the bacteria by high molecular weight anions or, in the case of dyes, more simply by shifting the pH so that the dye-protoplasm complex is no longer unionized, provided that the shift is within physiological limits.

In the case of bactericidal concentrations of the compound, it is not clear how far the bactericidal action can be allowed to go and yet permit revival. In many instances it is probable that it has not gone far, perhaps little beyond a preliminary sorption. When the compound is in bacteriostatic concentration only, of course, the cells remain alive for relatively long periods and multiply as soon as the inhibition is removed by neutralization or simple dilution. The significance of reversal of the antimicrobial effect lies in the inferences that may be drawn as to the nature of the antimicrobial activity.

Thespecificity of disinfectants. The marked specificity of the bacteriostatic and bactericidal activity of the dyes has been referred to above. The property of differential toxicity is not confined to these compounds alone, however, but is exhibited to some degree by many of the bactericidal chemicals. The hypochlorites, for example, while powerful germicides for most bacteria, have little effect on the tubercle bacillus, and it is of practical significance also that poliovirus persists in treated waters containing sufficient chlorine to destroy pathogenic bacterial contaminants.⁵³ general, the salts of the heavy metals are the least specific in their action and dyes the most, with other compounds lying between these two extremes. Certain slow oxidizing agents such as potassium dichromate exert a selective bacteriostatic effect on gram-negative bacteria, and iodine is more efficacious against these microorganisms. Similarly, among the long-chain aliphatic bases, the less strongly basic amines act on gram-positive bacteria for the most part, whereas the gram-negative organisms are more susceptible to the action of the stronger bases such as guanidines and quaternary amines. In general, the viruses are considerably more resistant to the activity of quaternary ammonium compounds than are bacteria. These compounds fail, for example, to inactivate vaccinia virus in dilutions as low as 1:1000 although they are bactericidal in many thousand-fold dilution.

influencing disinfection. The Factors process of disinfection or bacterial death is often, in part at least, a chemical reaction and is, therefore, subject to a variety of influences which affect the velocity of such reactions. The most important of these influences is the concentration of the reacting substances, i.e., the concentration of disinfectant and the numbers of bacteria present. The effective concentration of disinfectant is, in turn, dependent upon two other factors: first, the presence of moisture. which makes possible coagulation by heat and ionization of the bactericidal salts, and acts as a solvent and suspending medium in which there may be intimate contact between the disinfectant and the microorganism; second, the presence of extraneous organic matter.

Many chemical disinfectants act through

a combination with the protein of the cell and, if extraneous organic matter is present, will, of course, react with this inert material, thereby reducing the effective concentration. Disinfectants vary widely in the degree to which their bactericidal properties are affected by organic matter. The salts of the heavy metals are rapidly precipitated by organic material, while compounds such as phenol and the cresols are only slightly affected. The rate of destruction by heat is also affected by the presence of organic matter-organisms embedded in a mass of fecal material, for example, are protected from heat for a short time. The process of disinfection by germicides or by heat is influenced by temperature, the velocity of the reaction increasing with rise in temperature.

The pH likewise influences the rate of bacterial destruction not only by heat but by many chemical compounds, the velocity, in general, being least at neutrality and increasing with increase in acidity or alkalinity. A number of other factors, such as the presence of salts, ¹⁰⁸ affect the rate of disinfection but generally not sufficiently to be of practical importance.

From the practical point of view, the time of exposure of bacteria to a given disinfectant is of considerable significance and bears an inverse relation to the rapidity of killing. The time allowed for the destruction of bacteria is determined not only by the factors discussed above but also by the kind of bacteria that are to be killed. In certain cases the specificity of a disinfectant may be so marked that it must be taken into consideration. For example, the relative atoxicity of hypochlorite for the tubercle bacillus referred to above precludes its use in the disinfection of tuberculous sputum. Bacterial spores are much more resistant to heat and chemical disinfectants than are the vegetative cells, and considerably more time must be allowed for their destruction. The vegetative cells of some bacteria may be somewhat more resistant than those of others, but, for the most part, such differences are too small to be of practical significance.

The dynamics of disinfection.^{37, 98} Quantitative studies on the rate at which microorganisms are killed by lethal agents have indicated that in many instances the organisms die at a logarithmic rate; *i.e.*, if the logarithms of the numbers of viable organ-

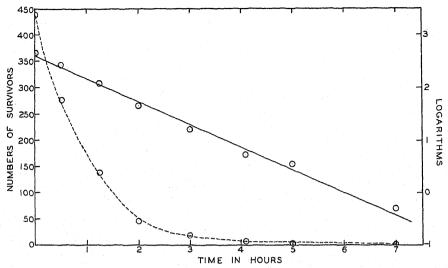

Figure 47. Death rate of anthrax spores treated with 5 per cent phenol. The dotted line is the arithmetic plot and the solid line the logarithmic plot. The negative logarithm was obtained by taking samples of several times the unit volume. (After Chick.)

isms are plotted against time, the points tend to fall on a straight line. This phenomenon has been observed in the death of both spores and vegetative cells under the influence of chemical disinfectants or moist heat and also occurs in the death of bacteria in old cultures. The velocity of the reaction, the slope of such a line, depends upon the concentration and kind of disinfectant, the

nature of the organisms—whether spores or vegetative cells—and other factors which influence the process of disinfection. This logarithmic rate likewise describes the course of a monomolecular reaction, and this fact has led some to conclude that bacterial death is a monomolecular chemical reaction. Although the killing of bacteria by some disinfectants is undoubtedly a

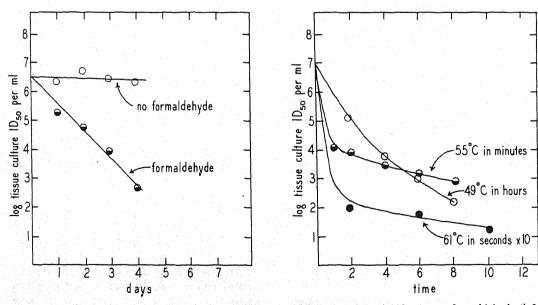

Figure 48. The inactivation of tissue culture foot-and-mouth disease virus by 0.009 per cent formaldehyde (*left*) and by heat (*right*). The formaldehyde inactivation is exponential over the indicated range, but deviation from an exponential rate during heat inactivation is marked, with increased heat stability at low survival levels. (Data from Bachrach, Breese, Callis, Hess, and Patty.)

chemical process, as for example the precipitation of constituent protein as proteinates of heavy metals, the evidence does not justify the conclusion that the reaction is monomolecular. The fallacy is the old one of confusion of correlation and causality under the slightly different guise of description and mechanism. Experimental evidence has indicated that while such semilogarithmic plots may often be fitted with a straight line, others are best fitted by sigmoid curves, the death rate being more rapid in the beginning in some cases and more rapid at the end in others or even highly irregular.

One of the more important determining factors is a graded biological resistance of the cells in the bacterial population, an explanation that is supported by general biological considerations. Undoubtedly the phenomenon of bacterial death is a complex of interrelated factors whose admixture with the mechanics of the mass law results in the parameters determined by mathematical means. Of practical importance, however, is the fact that in disinfection by chemicals and by heat there is a minority of cells, possibly more resistant, that survive long after the majority have perished and that must be destroyed in order to obtain complete sterilization. The determination of antiviral activity poses special technical problems because of the necessity for assay of viable agent by infectivity titrations,⁴⁷ and the effects of auto-interference when a large portion of the agent has been inactivated toward the end point (Chap. Four).

In any case, it is clearly not possible to extrapolate the exponential death rate to zero and assume that the time of exposure so indicated insures sterility; such an assumption resulted, for example, in incomplete inactivation of poliovirus by formalin in the preparation of vaccines. 106

The standardization of disinfectants. The relative bactericidal efficiency of the chemical disinfectants is a point of considerable practical importance. The value of a quantitative method for the determination of the killing power of germicides was recognized early in the development of bacteriology, and experimental investigation led to the establishing of a standardized technique which made possible the determination of the bactericidal power of a given chemical compound relative to that of phenol. The numerical value so determined is termed the phenol coefficient and is presumed to

indicate whether, and to approximately what extent, the unknown is a better or poorer germicide than phenol. Later methods of standardization have grown out of this procedure. The phenol coefficient of a disinfectant used against the typhoid bacillus is calculated as follows:

Divide the greatest dilution of the disinfectant capable of killing Salmonella typhi in 10 minutes but not in five minutes by the phenol dilution which so kills and divide these figures one into another. In order not to convey a false idea of the accuracy of the method the coefficient is calculated to the nearest 0.1 point if under 1, to the nearest 0.2 point if between 1 and 5, to the nearest 0.5 point if between 5 and 10, and to the nearest 1.0 point if between 10 and 20. The conditions regarded as standardized in the United States, the FDA phenol coefficient, have been defined by the Food and Drug Administration.

The effect of extraneous organic matter on the bactericidal power of a disinfectant is commonly taken into consideration by carrying out the test with and without added organic matter. Three per cent of dried fecal matter or dried yeast may be added to the bacterial suspension or the organisms may be suspended in 50 per cent serum. It is important to recognize that bacteria differ considerably in their resistance to phenol, staphylococci, for example, being much

Determination of the Phenol Coefficient*

more resistant than the typhoid bacillus, so that in strict accuracy it is necessary to specify "typhoid phenol coefficient," "pneumococcus phenol coefficient," etc.

The phenol coefficient criterion of antimicrobial activity has many defects, including failure to evaluate concentration effects, temperature coefficients, etc. In addition, the validity of a phenol coefficient determined for a nonphenolic disinfectant is open to serious question. In consequence, many variations of the procedure have been used. For example, the germicidal equivalent concentration test has been developed for the evaluation of the lethal activity of substances such as hypochlorites, in which concentrations giving the same killing pattern as those of a reference compound are determined. This kind of test is illustrated in the accompanying tabled example; here the activity of the unknown disinfectant in a concentration of 10 ppm is equivalent to that of the reference standard, NaOCl, in a concentration of 50 ppm.

Assay of the antimicrobial activity 103 of detergents is difficult because of the tendency of the test bacteria to become adsorbed to the walls of the test tube as a consequence of altered charge in the presence of the disinfectant. So-called use dilution tests have been employed for these substances in which a suspension of the test microorganism is dried on the surface of a carrier such as glass rods or rings, immersed in the disinfectant for varying periods, and subsequently cultured. Such methods are not new but were used many years ago by Koch and others who dried anthrax spores on silk threads, glass beads, etc., for testing bactericidal activity.

All of these methods of assay suffer from the fundamental defect of dependence upon a sterility end point, an end point which studies of the dynamics of the process of disinfection have shown to be highly questionable.

It is generally agreed that the rate of killing, *i.e.*, the reaction velocity constant, is a much more accurate measure than any value whose derivation depends upon a sterility end point. The relation between concentration of disinfectant and time required for killing is an exponential one, and the reaction velocity constant, k, is given by the expression:

 $k = C^n t$

where C is the concentration, n a constant characteristic for each disinfectant, and t is time. The temperature coefficient may, of course, be determined experimentally for each disinfectant. It will be clear that this kind of characterization of the bactericidal activity of a given compound is much more informative than the usual type of phenol coefficient, no matter how precisely the conditions of the test are defined. It is not, however, generally used for routine work.⁵⁰

The practical value of a disinfectant is not always indicated by tests made under the controlled conditions of the laboratory. Hydrogen peroxide, for example, may give a quite respectable phenol coefficient but, when applied to an abrasion, is so rapidly decomposed under the influence of tissue catalase that its germicidal powers are almost immediately exhausted. This has led to various kinds of infection prevention tests which have necessarily included the

[†]The time interval may vary from 30 seconds to two minutes.

matter of the toxicity of the disinfectant for tissue cells.

A given disinfectant may be so highly toxic for tissue cells that it has no practical value. Salle and his associates84 have proposed a "toxicity index" which takes into consideration not only the germicidal activity of a compound but its toxicity for tissue as well. For example, Witlin¹¹⁰ determined the concentration of bactericidal substances lethal for the chick embryo and calculated a toxicity index by using the concentration of the bactericide in grams per milliliter killing the test organism, Staphylococcus aureus, in 10 minutes but not in five as the numerator, and the chick embryo MLD in grams for the denominator. Representative values were: phenol (1:20)-1.18; $HgCl_2$ (1:1000) – 0.62; tincture of iodine-0.044; sodium hypochlorite-1.39; Mercurochrome (1:50)-13.3; and values

ranging as high as 9.1 for various organic mercurials. Spaulding and Bondi⁸⁷ have developed an infection-prevention-toxicity test in which the tip of a mouse tail is contaminated with bacteria, the tail dipped into the solution of disinfectant, and then the tip is removed and placed in the peritoneal cavity. The highest dilution of the disinfectant protecting 50 per cent of the mice is taken as the numerator, and the greatest concentration allowing survival (from poisoning) of the test animal is taken as the denominator, to give a ratio or infectionprevention-toxicity index. Such toxicity indexes are of considerable practical importance in the case of skin disinfectants.

The whole question of the evaluation of disinfectants is beset with many difficulties, both theoretical and practical, and to date remains an open one to which no entirely satisfactory answer has been supplied.

The Chemotherapeutic Drugs 23

Antibacterial activity as described previously is characterized by its manifestation in vitro, i.e., against the living microorganism but outside the body of the host in the case of the pathogenic microorganisms, and by the end point of bacterial death, a criterion of bactericidal activity. The feasibility of using antibacterial substances in vivo as chemotherapeutic agents is dependent primarily upon the phenomenon of specificity of action of such substances, specificity as regards selective action on the microorganism without significant harmful effects on the host. This idea is by no means new; it was the basis of Ehrlich's search for a "magic bullet," a compound strongly germicidal for a given microorganism yet sufficiently nontoxic that it could be injected in suitable amount to give effective concentrations in the tissues. His work, originally directed toward the therapy of African sleeping sickness of trypanosome etiology, was an attempt to retain the antimicrobial activity of arsenic compounds and at the same time reduce toxicity for the host, and culminated in the synthesis of salvarsan. The original work has, of course, been greatly extended and amplified both by Ehrlich and other workers through the preparation of other arsenicals, antimony compounds, and so forth.

Prior to 1940 the approach to chemotherapy of infectious diseases was fundamentally the same, a trial-and-error search for antimicrobial activity in vivo, followed by determination of the active portion of the molecule, and retention of this activity with coincident reduction of toxicity to the host by the synthesis and testing of a great number of related compounds. For example, the small but significant antimalarial activity of the substituted thionine, methylene blue, was exploited by the German workers in the development of Atabrine. A general practice, then, has been the routine testing of synthetic organic chemicals, especially dyestuffs and dye intermediates, for antimicrobial activity in vivo. This procedure led Domagk in 1935 to the observation of the marked chemotherapeutic activity of the dye Prontosil in experimental streptococcus infections. Routine procedure led to identification of the active portion of the molecule, p-aminobenzene sulfonamide (sulfanilamide), and the synthesis of a great number of related compounds known as the sulfonamides. While of great practical significance, in that these compounds were the first found to be effective in bacterial infections, the discovery and study of the sulfonamides marks a great step forward in that (1) there is now available for the first time a rational theory of chemotherapy (see below) and (2) it is now clear that effective chemotherapeutic agents are usually bacteriostatic rather than bactericidal.

As implied earlier, the differentiation of bactericidal and bacteriostatic activity is essentially one of convenience based on the concentration differential of the active substance, i.e., when the difference between the two end points (growth inhibition and death) is great, the compound is regarded as primarily bacteriostatic, but when it is very small the bacteriostatic zone is so limited as to appear unimportant and the term bactericidal is usually applied. Compounds that are practical chemotherapeutic agents are, like the triphenylmethane dyes, bacteriostatic substances.

The chemotherapeutic activity of a substance employed in bacteriostatic concentrations rests in large part upon the host facet of the host-parasite relationship. Upon invasion of a susceptible host with a pathogenic microorganism, a series of mechanisms grouped under the head of resistance or natural immunity (Chap. Nine) become functional. The relationship between the host and the microorganism, then, is a dynamic one which is affected by lesser factors influencing one or the other. Antitoxin therapy, for example, reinforces the immune response of the host, tipping the balance against the microorganism. Similarly, the administration of a substance that does not interfere to a significant extent with the mechanisms of natural immunity, but does prevent the microorganism from proliferating within the tissues, also tips the balance against the microorganism to allow its destruction and elimination by the host. Formerly the role of host defense was not fully appreciated, and the significance of the failure to take this factor into account is underscored by the fact that sulfonamide compounds were investigated by one of the outstanding research laboratories as early as 1912 and discarded because they showed little bactericidal activity.

At the present time a number of highly effective chemotherapeutic agents are known. They may be divided into two groups: those that were originally synthetic organic chemicals and those that are derived from living organisms. The latter may be divided again into two subgroups: those substances that are formed by certain species of bacteria and those that are formed

by actinomycetes and molds. The structures of some of the naturally occurring substances are known, and one is prepared on a commercial scale by synthesis. All are characterized by being primarily bacteriostatic and by a specificity of action manifested not only by a lack of toxicity for the host, but also by differential activity with respect to species, and sometimes strains, of microorganisms.

SYNTHETIC COMPOUNDS

The synthetic chemotherapeutic agents, with the exception of the sulfonamides, are used in the therapy of diseases produced by the animal parasites and in the treatment of tuberculosis and leprosy. The first group is considered elsewhere (Chap. Thirty-four). The chemotherapeutic agents having greater or lesser efficiency in the treatment of infections with the acid-fast bacilli fall into four groups, viz., the sulfones, the aminohydroxybenzoic acids, the thiosemicarbazones, and the derivatives of pyridine carboxylic acid.

The sulfones. The antituberculous activity of the parent compound of the sulfone group, 4,4'-diaminodiphenylsulfone (DDS, DADPS, Dapsone), was reported by French workers in 1940. Various disubstitution products, Promin (sodium 4,4-diamino-diphenyl sulfone-N, N' didextrose sulfon-Promacetin (sodium 4,4'-diaminodiphenylsulfone-2-acetylsulfonamide), Diasone (disodium formaldehyde sulfoxalate diaminodiphenyl sulfone), and Sulphetrone $[\gamma$ -phenyl-N-propylamino] (4.4'-bis)phenylsulfonetetrasodium sulfonate) have been prepared in an effort to reduce toxicity and increase solubility and activity. None has been particularly successful, possibly in part because it is probable that the active derivatives are hydrolyzed to DDS in vivo and the activity is attributable to that of the parent compound. In general, the activity and toxicity of the sulfones are such that they are not highly effective chemotherapeutic agents and are not generally used in the treatment of tuberculosis since better drugs are available. However, these compounds are useful in the treatment of leprosy.

Aminohydroxybenzoic acids. Of these compounds, p-aminosalicylic acid (PAS) is the best known. Its activity against the

tubercle bacillus was reported in 1944, based on the observation made three years earlier that the oxygen uptake of the tubercle bacillus is increased in the presence of salicylates and benzoates. It is relatively nontoxic and is currently most useful when administered together with streptomycin, since it markedly reduces the tendency of tubercle bacilli to become resistant to the antibiotic (Chap. Thirty-one).

Many derivatives have, of course, been prepared, but of these only one, phenyl p-aminosalicylate (FR 7), first described in 1951, shows greater activity than PASabout ten-fold when given subcutaneously.

Thiosemicarbazones. These compounds, described as possible chemotherapeutic agents in 1946, are more active against the tubercle bacillus than are the sulfones and PAS. The parent compound (TB I) is not particularly active, but p-acetaminobenzaldehyde thiosemicarbazone (Tibione, TB 1/698, Conteben, Thiacetazone, Amithiozone) has considerable activity and has been widely used in Europe, where it has been found reasonably effective in most forms of tuberculosis. It is, however, toxic (gastrointestinal disturbances, anemia, liver, and kidney damage), and the incidence of severe side reactions is high. Many derivatives of this structure have been prepared, most of them involving alteration in the character and position of the subordinate grouping on the benzene ring. Of these, only the p-ethylsulfonyl compound (TB III) appears promising. Of the three isomers of the pyridine analogue of Tibione, the β and γ isomers have shown promise in experimental tuberculosis.

Certain of the thiosemicarbazones have been found to have activity against the poxviruses. The compound N-methylisatin β-thiosemicarbazone (methisazine, boran) has been of particular interest, since it has been found to be prophylactic, though not therapeutic, for smallpox in man, as well as antiviral in tissue cultures and prophylactic in experimental vaccinia.83, 104 The mechanism of the antiviral activity is quite uncertain; it apparently does not affect the synthesis of viral DNA or protein, but interferes with a step required for maturation, for the virus particles produced are noninfective.

Pyridine carboxylic acid compounds. The tuberculostatic activity of nicotinamide was reported in 1945; the activity is not, as stated by some workers, a function of

5.

isonicotinic acid hydrazide

1-isonicotinyl-2-isopropylhydrazine

its vitamin activity, since nicotinic acid has no antibacterial activity. Isonicotinic acid hydrazide (Rimifon, Nydrazid, Neoteben, INH) and 1-isonicotinyl-2-isopropylhydrazine (Marsilid) have been found to have marked activity, several-fold greater than streptomycin in experimental tuberculosis. Further study has shown that activity is not necessarily limited to immediate derivatives of nicotinamide, but may be associated with the pyridine structure, and pyrizinamide (Aldinamide), for example, has chemotherapeutic activity.

Nitrofurans.70 Furfural and related compounds have long been known to have antibacterial activity. The activity is greatly increased by substitution of a nitro group in the 5-position, and a great many derivatives have been prepared by substitution of various side-chains in the 2-position. The first of these to show promise as a chemotherapeutic agent was 5-nitro-2furaldehyde semicarbazone, or nitrofurazone (Furacin). Other nitrofurans include N-(5nitro-2-furfurylidene)-1-amino hydantoin, or nitrofurantoin (Furadantin), and N-(5-nitro-2-furfurylidene)-3-amino-3-oxalolidone, or furazolidone (Furoxone). As a group, these compounds have a broad antimicrobial spectrum, affecting certain fungi and protozoa as well as bacteria. Nitrofurazone has been used as a topical application in man in the therapy of burns, etc. Nitrofurantoin is excreted in the urine following oral administration and is an effective chemotherapeutic agent in urinary tract infections. Furazolidone remains in the intestinal tract following oral administration and is used in the treatment of enteric infections of bacterial etiology, such as Salmonella and Shigella, and is also a trichonomacide. These and other nitrofurans are also used in the therapy of various infectious diseases of domestic animals.

Sulfonamide compounds. 33, 100 cated above, p-aminobenzene sulfonamide was the first of the chemotherapeutic substances effective in bacterial infections other than the treponematoses that are susceptible to treatment with arsenicals. The term sulfonamide is generally taken to include the parent compound and its derivatives. Several thousand sulfonamides have been prepared, usually by substitution in the amido group attached to the sulfone radical, but some, such as Sulfathalidine and Sulfasuxidine, contain substitutions in the amino group attached directly to the benzene ring. These last are poorly absorbed from the intestinal tract and have considerable utility in some infections confined to the lumen of the bowel, such as bacillary dysentery. Of all the compounds prepared, only a few have been generally used. They are effective against microorganisms such as the streptococci, staphylococci, pneu-

6. NH2 NH₂ NH₂ ĊН ĊН H SO₂—NH₂ sulfanilamide sulfadiazine sulfapyridine NH_2 NH₂ NH_2 CH₃ CH₃ CH₃ CH₂ H sulfamethazine sulfamerazine Gantrisin, Gantrosan, sulfisoxazole, sulfafurazole

mococci, gonococcus, meningococcus, the plague bacillus, the dysentery bacilli, but are relatively ineffective against microorganisms of the Salmonella group, including the typhoid bacillus, rickettsiae, and others.

There appears to be little qualitative difference among these compounds so far as antibacterial activity is concerned, but they differ with respect to solubility, rates of absorption and excretion, and other factors. In general, they are only sparingly soluble in water, and solubility increases with alkalinity. On absorption a portion of the drug is inactivated by combination with plasma protein, and a portion acetylated to an inactive form in the liver, and both active and inactive drug are excreted in the urine. When the urine is acid and its volume low, the drug may accumulate in the kidney with resulting damage. The administration of mixtures of sulfonamides, such as triple sulfa containing sulfadiazine, sulfamethazine and sulfamerazine, has no direct therapeutic advantage, but reduces precipitation in the kidney since the solubility of each is independent of the presence of the others.

At the present time the sulfonamides are somewhat neglected as a consequence of the glamor of the antibiotics. While in many, but not all, instances they are less potent therapeutic agents, the sulfonamides will do just as much, more simply and cheaply, though possibly more slowly, than the antibiotics. They have the additional advantage that their administration produces less drastic changes in the normal flora and consequently less secondary infection with drug-resistant microorganisms.

THE ANTIMETABOLITE THEORY OF ANTIBACTERIAL ACTIVITY⁷⁶, 85, 111, 112

Competitive inhibition of enzyme reactions in which a structural analogue of the substrate competes with the substrate for the enzyme was described by Quastel and Wooldridge in 1928. They demonstrated the inhibition by malonic acid of the oxidation of succinic acid to fumaric acid catalyzed by succinic dehydrogenase in the presence of a hydrogen acceptor, and reversal of the inhibiting effect by excess succinate. Malonic acid differs from the

substrate in that it is a 3- instead of a 4-carbon dicarboxylic acid.

If such a reaction is an essential part of the metabolic processes of a bacterium, the inhibitor exhibits antibacterial activity. The immense practical significance of this was pointed up in the observation by Woods in 1940 that the antibacterial activity of sulfonamide is specifically inhibited by p-aminobenzoic acid, a compound that is required as a bacterial vitamin by a number of organisms, including Clostridium acetobutylicum, Acetobacter suboxydans, and some strains of the diphtheria bacillus. The close similarity in the structure of paminobenzoic acid and p-aminobenzene sulfonamides will be obvious from the structural formulas in 6. That p-aminobenzoic acid is required by some bacteria suggests that it is involved in some essential metabolic reaction, and it was suggested by Woods and by Fildes that the action of the sulfonamides on bacteria is the result of a competition of these compounds with an essential bacterial metabolite, p-aminobenzoic acid. This inhibitory effect of sulfonamides is reversible and can be antagonized by excess p-aminobenzoic acid. This has the practical value of allowing successful blood culture from individuals undergoing sulfonamide therapy by inclusion of p-aminobenzoic acid in the culture medium (5 mg. per 100 ml.).

The generalization follows that essential physiological reactions of the microorganisms may be inhibited by analogues of metabolites, and that such antimetabolites might be expected to show antibacterial activity. The plausibility of such a hypothesis is underscored by the essentially growth-inhibiting rather than lethal effects of chemotherapeutically effective substances on pathogenic microorganisms under physiologically tolerable conditions. This hypothesis assumes primary importance by providing, for the first time, a rational basis for the chemotherapy of infectious disease.

Enzyme inhibition. This theory is substantiated by impressive evidence. It has also been extended by the production of symptoms of vitamin deficiency in higher animals receiving vitamin analogues (pyrithiamine, glucoascorbic acid, isoriboflavin, β -acetylpyridine, etc.) and by encouraging results in the treatment of certain kinds of cancer with folic acid antagonists and with purine antagonists such as 6-mercapto-

purine, 2,6-diaminopurine, 6-chlorpurine, and pyrazolo purines. Enzyme inhibition is also the basis of the activity of a number of narcotics and of certain chemical warfare agents and insecticides such as tetraalkyl phosphates, dialkyl p-nitrophenylphosphates, and dialkyl fluorophosphates, which irreversibly inhibit esterases, including acetylcholinesterase.

Generally, enzyme inhibition may be of a number of kinds, viz., competitive inhibition of the kind typified by the malonatesuccinate competition for succinic dehydrogenase noted above, noncompetitive inhibition in which the inhibitor combines with the enzyme at a site other than the active site, and, less commonly, other kinds of inhibition in which, for example, the inhibitor combines with the enzyme-substrate complex, removes essential ions by chelation, and so on. Competitive inhibition may be distinguished by plotting the degree of inhibition against substrate concentration; in the competitive type of inhibition this is a linear function of substrate concentration, i.e., inhibition is inversely related to the ratio of substrate concentration to inhibitor concentration, while in the noncompetitive types in which the inhibitor does not combine with the enzyme at the active site, the affinity of the enzyme for substrate is not altered, and the rate of the enzyme-catalyzed reaction is not related to the ratio of the concentration of substrate to that of inhibitor. Such enzyme inhibitions may be reversible, or partially or completely irreversible.

The folic acid system. Inhibition among microorganisms may be illustrated by elaboration of the sulfonamide-p-aminobenzoic acid relationship. As described elsewhere (Chap. Five), p-aminobenzoic acid is an intermediate in the synthesis of folic acid, and folic acid is, in turn, a precursor of the formyl-folic acid (folinic acid) coenzyme. The synthesis of folic acid from p-aminobenzoic acid, glutamic acid, and the pteridine nucleus is antagonized by sulfonamides, and the inhibition is competitive. Sulfonamides do not, however, inhibit the conversion of folic acid to folinic acid; rather, this reaction is inhibited noncompetitively by 4-amino derivatives of folic acid, such as aminopterin and α -methopterin. The latter inhibition, then, prevents folic acid from acting as a formylating agent in 1carbon transfer reactions involved in the synthesis of at least some amino acids and nucleic acids.

Differences in the effect of sulfonamides on different kinds of microorganisms may be resolved in terms of their synthetic abilities, and it has been suggested that three general groups may be distinguished. The first is the gram-negative bacteria, which do not require preformed folic acid, and are inhibited by sulfonamides, and the inhibitory effect is not reversed by added folic acid. The second includes the gram-positive bacteria that do not require preformed folic acid, are inhibited by sulfonamides and the inhibition is reversed by folic acid. The third group, also gram-positive bacteria, is made up of those requiring preformed folic acid for growth and not sensitive to sulfonamides.

Limiting systems. In some instances analogues may compete with metabolites acting as coenzymes, but in general the evidence indicates that the competition occurs when the metabolite acts as a substrate rather than as a coenzyme. As a substrate, the metabolite is synthesized into a more complex molecule which functions as a coenzyme, or it may be degraded prior to synthesis. Further, various apoenzymes may compete, for folic acid for example, and the effective ratio of inhibitor to metabolite depends upon which enzyme system is involved. The requirements of different systems vary, and one of them is the limiting factor.

The sulfonamide sensitivities of bacteria which do not require p-aminobenzoic acid or folic acid for growth may be abolished by including the amino acids, purines, and pyrimidines in the culture medium which are synthesized in the reactions catalyzed by folic acid derivatives. When the necessity for the functioning of the limiting system is removed by supplying its end product, the concentration of antimetabolite is no longer inhibitory. If, however, the antimetabolite concentration is increased, inhibition is again apparent, another enzyme system has become the limiting factor, and again the inhibitory effect may be removed by supplying the end product of that system. Thus, the end products of the several systems involved which produce sparing effects can be arranged in an order. In the case of the colon bacillus, for example, methionine, purines, serine, and finally thymine or thymidine constitute such a series of which each member is dependent upon those preceding it. In this way studies of the nature of substances antagonizing the activity of the inhibitor may shed considerable light on the nature of the relevant reactions of synthesis.

Other inhibitors. There are a number of other instances of inhibition by analogues of essential metabolites of bacteria, produced by replacement of a carbonyl group with a sulfonic acid or sulfonamide radical or by a ketone, by substitution in the ring system of aromatic compounds, the replacement of alkyl side chains of ring systems with halogens, etc. Such are the sulfonic acid and sulfonamide analogues of nicotinic acid, pantolyltaurine (thiopanic acid), and pyrithiamine, the pyridine analogue of thiamine.

Effective chemotherapy of virus infections would appear to fall within this general concept, in the sense of selective inhibition of viral synthesis in the infected cell. $^{5, \, 51, \, 105}$ The prophylactic activity of N-methylisatin β -thiosemicarbazone noted above presumably has such a basis. Other compounds having activity have been studied also, notably vitamin B_{12} , guanine, and thymine analogues.

The inhibition of many picornaviruses in cell culture by 2-(hydroxybenzyl) benzimidazole and by guanidine¹⁰⁵ appears to be relatively specific, for these compounds are quite nontoxic for the host cells, and viruses of other groups, including poxviruses, herpesviruses, myxoviruses, reoviruses, and arboviruses, are not affected. The nature of the antiviral activity is not well understood, but there is reason to suppose that these agents function by inhibiting the production of virus-induced RNA polymerase.

It may be noted in passing that various other substances inhibit cellular RNA biosynthesis, e.g., actinomycin D and 5,6-dichloro-1- β -D-ribofuranosylbenzimidazole, the latter by inhibiting the incorporation of adenosine into cellular RNA. Such inhibitors, particularly the former, have been useful in the elucidation of RNA function in biosynthetic reactions.

Halogenated deoxyuridines have been found to inhibit the replication of the DNA viruses of herpes simplex, vaccinia, and varicella⁷⁷ in cell culture and have very considerable utility in the chemotherapy of herpes keratitis in man. The halogen substitution is in the 5-position. The fluorine

compound has been found to inhibit the synthesis of thymine monophosphate and is not incorporated into the DNA. The iodine and bromine derivatives inhibit the utilization of thymine compounds, but not their synthesis, and are incorporated in DNA. Of these, 5-iodo-2'-deoxyuridine (IDU) has been used for therapeutic purposes in man and has been found to be effective in the treatment of experimental vaccinial keratitis.⁵²

Other antiviral agents function by inhibiting the initial absorption and/or penetration of the virus particle and are essentially prophylactic rather than therapeutic. Receptor-destroying enzyme (RDE) is effective in the prevention of influenza virus replication by depolymerization of the receptor substrate on the surface of the host cell, and some mucopolysaccharides of microbial origin presumably function by offering an alternative to the host cell receptors. Considerable interest has attached to the antiviral activity of amantadine (1adamantanamine HCl) for the influenza virus; its activity appears to be prophylactic rather than therapeutic in experimental infections in animals30 and man,91 but the nature of the inhibitory effect is not known.

Inhibition may also be indirect or nonspecific in the sense that compounds other than structurally related analogues may be inhibitory. In the first instance the substance applied as an inhibitor may be inactive but metabolized to an active form. The wellknown inhibitory effect of fluoro-acetate is apparently due to its metabolic conversion to fluorocitric acid, which is an inhibitor of aconitase. There is evidence also that exchange reactions with the coenzyme may occur with some of the pyridine compounds; isonicotinic acid hydrazide has been found to undergo exchange with nicotinamide, and the corresponding NAD analogues have been isolated. Inhibition by structurally unrelated compounds occurs also as in the inhibition of invertase by certain basic dyes: sucrose and other sugars compete with the dye for the enzyme, suggesting that a variety of chemically different substances having appropriately distributed charges may compete for acidic or basic groups on the enzyme to produce inhibition of its activity.

The nature of the antibacterial activity of enzyme inhibitors cannot be sharply differentiated from the antibacterial effects of substances having utility as disinfectants. While the lethal action of disinfectant substances is a net effect, as pointed out earlier, probably the most important single effect, though not necessarily always the quantitatively predominant one, is inactivation of enzyme systems. Thus, the affinity of heavy metals for sulfhydryl groups, including those of enzymes, is well known, and the bisphenols, such as hexachlorophene, strongly inhibit succinoxidase, cytochrome oxidase, and lactic dehydrogenase; still other examples of this kind of effect of disinfectants have been noted above.

ANTIBIOTIC SUBSTANCES^{23, 28, 115}

The mutual relationships occurring among the microorganisms are analogous to those well known among other living organisms, ranging from synergistic and beneficial associations to antagonistic relationships. Synergism, the relation in which a group of two or more kinds of microorganism has capabilities greater than the sum of those of the members of the group considered separately, is apparent in many situations, as different as the cyclic transformations of organic matter in the soil, and the dual or multiple etiology of infectious diseases such as swine influenza or gaseous gangrene.

The antagonistic relationship is often apparent between saprophytic and parasitic pathogenic microorganisms. In a general way, most pathogenic microorganisms are closely adapted parasites, poorly equipped to survive the rigors of intense competition with mixed microbial flora outside the body of the host. This appears to be the basis of the ability of the typhoid bacillus, for example, to survive for two to three weeks in sterile water, but only a few days in natural waters and even less in polluted waters. Similarly, the pathogenic microorganisms present in the bodies of persons dead of infectious disease, with the exception of the relatively rare spore-forming pathogens such as the anthrax bacillus, are unable to survive in the soil, and there is no hygienic objection to earth burial of such bodies.

Thus the microbial population, both animal and plant, of natural habitats such as soil and water, is determined by the

mutual relationships among the members of the population as well as other environmental conditions. The pathogen appears as a newcomer, too poorly adapted to establish an ecological niche in such habitats, and is unable to survive.

The antagonistic relationship is often attributable to the elaboration of substances by one kind of microorganism which are toxic or inhibitory to other kinds. The bluegreen pigment pyocyanin, a phenazine comproduced bv Pseudomonas aeruginosa (Ps. pyocyaneus), is actively toxic for very many kinds of bacteria and was, in fact, known as early as 1860 as the chloroform-soluble substance giving color to the "blue pus" of pyogenic infections with this microorganism-and before bacteria were known to be etiologically related to disease.

Such antimicrobial substances, originating as products of metabolism of living organisms, are known as antibiotics. 14 Such substances, elaborated under natural conditions in environments such as soil, which contains enormous numbers of a wide variety of microorganisms, play a significant role in microbial ecology. 107 In retrospect, saprophytic microorganisms present in soil seem a self-evident possible source of antimicrobial substances affecting pathogenic bacteria with some specificity, but the first antibiotic applicable to the treatment of infectious disease, penicillin, was not discovered until 1929 by Fleming. Since different kinds of bacteria differed in their sensitivity to its growth-inhibiting activity, penicillin was regarded as useful only in the preparation of selective mediums for the primary isolation of bacteria resistant to it such as Hemophilus species. It was not until 1940 that the concept of selectivity of action was extended to include man, with the consequence that its lack of toxicity for man in concentrations effectively inhibiting the growth of pathogenic microorganisms in vivo led to its use as a chemotherapeutic agent.

It is a common experience of those examining large numbers of isolation plates to find colonies of microorganisms surrounded by zones of no growth of other kinds of microorganisms present in the culture. It is but a single step from such observations to the inoculation of nutrient medium in a petri dish with a test bacterium so that a uniform film or growth will develop,

followed by a second inoculation with a rich source of varied microbial flora, commonly soil, by the streak or other dilution method to give isolated colonies. After incubation the culture is examined for halo-like zones of growth inhibition of the test organism about colonies growing up from the second inoculation. When such zones are observed. the appropriate colony is subcultured and the subculture tested for the presence of soluble growth-inhibiting activity for the test bacterium. The activity may be purified by various appropriate chemical methods and tested for both antimicrobial activity and toxicity to an experimental animal. If the toxicity is sufficiently low in relation to antimicrobial activity, it is tested for chemotherapeutic activity in experimental infections.

This procedure is relatively simple and so has been widely applied with the demonstration of many hundreds of kinds of antibiotic activity. Fungi, actinomycetes and molds, have been the most prolific source of antibiotics, although some are of bacterial origin. Unfortunately, the great majority of these are toxic, some highly toxic, to animals and are discarded from consideration as possible chemotherapeutic agents. Nevertheless, some 340 useful and potentially useful antibiotics are described in one compilation,88 of which some 20-odd are in active use. All show a greater or lesser degree of specificity of action on different kinds of bacteria, often associated with the Gram staining reaction, and the range of kinds of bacteria sensitive to the action of an antibiotic is spoken of as its "spectrum" of activity. Of the many antibiotic substances, only the most common will be considered here.

Antibiotic substances from bacteria. A variety of antibiotics are formed by the aerobic sporulating bacteria of the genus Bacillus. The first of these to be studied as a chemotherapeutic agent was isolated by Dubos in 1939 from *B. brevis*, and found to be an alcohol-soluble, water-insoluble polypeptide which was named tyrothricin.

Further investigation made possible its separation into two components, gramicidin and tyrocidin, of somewhat different properties though both contain "unnatural" amino acids of the d series. Gramicidin is a large cyclopeptide containing relatively large amounts of tryptophan and is effective only on gram-positive bacteria. A

closely similar substance, gramicidin S, is formed by a thermophilic variety of B. brevis which differs in that it has considerable activity against gram-negative bacteria and is a cyclopeptide hydrochloride with one free amino group, no free carboxyl, and one hydrochloride residue, made up of one residue each of *l*-ornithine, *l*-proline, *l*-valine, l-leucine, and d-phenylalanine. Tyrocidin is active against both gram-positive and gram-negative bacteria in vitro, but its activity is almost completely inhibited by serum proteins. These antibiotics are surface-active substances, and their antibacterial activity is perhaps attributable to their destructive effect on the cell wall of the bacterium.

A number of antibiotic substances have been isolated from strains of B. subtilis which vary somewhat in their properties and antibiotic activity, though all appear to be polypeptide in nature. Subtilin is effective chiefly on gram-positive bacteria and certain of the acid-fast bacilli. It has low toxicity and is effective in the therapy of experimental infection of mice with pneumococci and guinea pigs with anthrax. Bacitracin is similar to subtilin and effective on gram-positive bacteria, but its utility is limited by its nephrotoxicity. Bacillin is highly active on both gram-positive and gram-negative bacteria in vitro and is only moderately toxic, but, like tyrocidin, its activity is destroyed by blood and it is completely ineffective as a chemotherapeutic agent. Eumycin does not affect gram-negative bacteria but has in vitro activity against the diphtheria and tubercle bacilli and some of the fungi. Its toxicity is low but its therapeutic efficiency is not known. Licheniformin resembles subtilin in its properties and is regarded by some workers as identical with

Other antibiotics produced by bacteria are designated collectively as bacteriocins, 48,69 and more specifically as colicins, megacins, etc. Some of the bacterial pigments show antibiotic activity, including violacein from Chromobacter violaceum, phthiocol formed by the tubercle bacillus, and iodinin from Chromobacter iodinum.

Antibiotics produced by higher fungi.¹⁰ So far the most prolific source of chemotherapeutic antibiotics has been the higher fungi, that is, certain molds but especially the actinomycetes of the genus Streptomyces. These substances are relatively

simple compounds of molecular weights of less than 1000. Some of those which are toxic to animals and have no chemotherapeutic potentiality have been useful in other ways. Actinomycin A, for example, is a relatively specific inhibitor of RNA synthesis because it blocks the action of DNA-dependent RNA polymerase. Since this agent complexes with guanine in double-stranded DNA, RNA-primed syntheses are not inhibited, thus allowing the separation of viral RNA synthesis from that of the host cell.

Penicillin. 13, 95 Penicillin is not a single substance, but a group of closely related compounds differing from the parent β lactam monobasic carboxylic acid with respect to the side chain. These substances are formed by Penicillium notatum, 22 other species of Penicillium, and seven species of Aspergillus. The six common naturally occurring forms are shown in the accompanying table. Two other penicillins are produced by biosynthesis. One is cephalosporin N, produced by a species of Cephalosporium, which has been shown to be (D-4-amino-4-carboxy-n-butyl) penicillin. The other is penicillin V, phenoxymethyl penicillin, which is formed by P. chrysogenum when N-2-hydroxyethyl phenoxyacetamide is supplied as a precursor, which, in contrast to other penicillins, is stable as the free acid.

In addition, various relatively insoluble, and therefore less readily excreted, forms of penicillin have been prepared, including benethamine (N-benzyl- β -phenylethyl penicillin), hydrabamine (N,N' dihydrobutyl ethylenediamine dibenzyl penicillin) and benzathine (Benzethacil, Bicillin) (N,N'

dibenzyl diethylenediamine penicillin G.). Of these various forms of penicillin, penicillin G (phenacetyl penicillin) is the one generally available as a stable salt because it is most readily produced on a large scale.

The alteration of penicillins produced by fermentation to give "synthetic" penicillins has resulted in the preparation of a number of compounds having valuable properties. The phenoxy compounds include α -phenoxymethyl, α -phenoxyethyl, and α -phenoxypropyl penicillins, 109 which are acidresistant and can be given by mouth. A compound prepared from naturally formed 6-aminopenicillanic acid, $6[D(-)\alpha$ -aminophenylacetamido] penicillanic acid (Penbritin), is also acid-resistant and, in addition, has a considerably broader spectrum of activity than the other penicillins.^{79, 96} Special interest has attached to sodium 6-(2,6-dimethoxybenzamido) penicillinate (Celbenin, methicillin, Staphcillin), because the alteration in its structure is sufficient that it is not destroyed by penicillinase and is, therefore, effective against penicillinresistant staphylococci.61

Penicillin is produced by biosynthesis,¹⁷ although it has been synthesized, not because of the complexity of the molecule, but because it is relatively unstable. The synthetic product is not yet competitive with that produced by fermentation.

Naturally Occurring Penicillins

NAME	SYNONYM	SOURCE	R
Penicillin F Dihydro F penicillin	Penicillin I Gigantic acid	P. notatum P. chrysogenum A. giganteus	$CH_3CH_2CH = CHCH_2$ $CH_3CH_2CH_2CH_2CH_2$
Flavicin Flavicidin Penicillin G	F type Penicillin II	A. flavus P. notatum P. chrysogenum	$CH_3CH = CHCH_2CH_2$ CH_2
Penicillin X	Penicillin III	P. notatum P. chrysogenum	$HO \longrightarrow CH_2^-$
Penicillin K	Penicillin IV	P. notatum P. chrysogenum	CH ₃ CH ₂ CH ₂ CH ₂ CH ₂ CH ₂ CH ₂

Penicillin is most active on gram-positive bacteria, but some gram-negative forms such as the gonococcus and meningococcus are susceptible to it, as are most spirochetes. It appears to act primarily as a bacteriostatic agent though high concentrations may be bactericidal. In general it is more active than the sulfonamides and less so in vitro than the triphenylmethane dyes.

Streptomycin. This antibiotic is formed by Streptomyces griseus and was isolated by Waksman in 1943. It is a basic glucoside and may be changed to dihydrostreptomycin by hydrogenation. The structural formula of dihydrostreptomycin is shown in 7, the starred carbon indicating the point at which hydrogen is added; in streptomycin this alcohol group is an aldehyde. These substances differ from penicillin in their activity in that they are effective on gram-negative bacteria and also on the tubercle bacillus. The susceptibility of bacteria to streptomycin is variable from strain to strain, and the sensitivity of the infecting organism, particularly in the case of green streptococci, should be tested. A serious drawback to the use of this antibiotic is the facility with which sensitive bacteria become resistant to it.

Streptomycin and dihydrostreptomycin do not differ in antibacterial activity from one another except that some strains of Salmonella are less sensitive to the dihydro compound.

Chloromycetin). This antibiotic, formed by Streptomyces venezuelae, was described in 1947 by Ehrlich and his associates. Its structure has been determined, and it is now prepared by synthesis. the only antibiotic so prepared on a large scale. The structure is of some interest because aromatic nitro compounds and derivatives of dichloracetic acid are relatively rare in nature (8). This antibiotic. together with the tetracyclines, makes up the group of "broad-spectrum antibiotics," i.e., those that are effective against a wider variety of microorganisms than either penicillin or streptomycin. Chloramphenicol is effective not only against the gram-positive bacteria, but also the gram-negative bacteria and the typhoid bacillus in particular. It is also active against the rickettsiae and the microorganisms of the psittacosis-

8.

lymphogranuloma group. Its efficacy in typhoid fever is unique, and it is the drug of choice in the treatment of this disease. It is, however, relatively ineffective in bacillary dysentery.

Chloramphenicol is relatively nontoxic by mouth and is effective by the oral route, for it is readily and almost completely absorbed from the gastrointestinal tract, and only occasionally nausea, vomiting, or diarrhea is produced. There have, however, been a number of reports of aplastic anemia following the administration of this antibiotic, perhaps to be expected since it is a nitro compound.

Tetracyclines. Chlortetracycline (Aureomycin), produced by Streptomyces aureofaciens, and oxytetracycline (Terramycin), produced by Streptomyces rimosus, were found independently, the former in 1948 by Duggar and his associates and the latter by Finlay and his associates in 1950. It soon became apparent that the two resembled one another closely, and it was subsequently shown that they are isomorphic tetracycline compounds, chlortetracycline containing nonionic chlorine at the sixteenth carbon and oxytetracycline a hydroxy group on the twelfth carbon. The parent compound, tetracycline (Achromycin, Polycycline,

Chlortetracycline has a Cl attached at *, while oxytetracycline has a hydroxyl group attached at **.

Tetracyn, Stechlin, Panmycin), is obtainable by catalytic reduction of chlortetracycline and also by fermentation by a species of Streptomyces.

Chlortetracycline is distinguished by its golden yellow color. The chloride is stable, but in neutral solution the antibiotic decomposes relatively rapidly at incubator temperatures. This makes for some difficulty in the microbiological assay of its activity, and cultures need to be observed after short periods of incubation. Its bacterial spectrum is closely similar to that of chloramphenicol, but it is not as effective in the treatment of typhoid fever.

Chlortetracycline is relatively nontoxic on oral administration; untoward reactions are mild and include nausea, vomiting, and diarrhea. Parenteral inoculation is painful and results in an erythematous tender area at the site of intramuscular inoculation. In practice the requirement for parenteral administration is limited, since the drug is well absorbed from the gastrointestinal tract.

Demethylchlortetracycline, having one less methyl group, reaches blood levels more slowly, but renal clearance is low and blood levels tend to persist. It is reported to have equal, if not greater, antibacterial activity than the parent compound.21

Oxytetracycline is a white substance which in neutral solution is more stable than chlortetracycline but resembles it closely in antibacterial activity, efficacy when given by mouth, and other factors. In inhibitory concentrations it blocks the utilization of ribonucleic acid reserves that are lost to the surrounding medium after depolymerization to mononucleotides. It also inhibits respiration in the presence of 4-carbon dicarboxylic acids, pyruvate, tricarboxylic acids, and α -ketoglutarate.

The parent compound, tetracycline, does not differ significantly from the chlor- and oxy-derivatives in antibacterial activity.

Chemical classification. 1, 67 While antibiotics are chemically diverse, most of them fall into three general groups, viz., (1) those derivable from amino acids, including penicillin, chloramphenicol, bacitracin, polymyxin, and cycloserine; (2) those derivable from acetate, including the tetracyclines, griseofulvin, the erythromycin group of macrolides, and the conjugated polyenes, amphotericin B and nystatin; and (3) those derivable from sugars, including streptomycin, kanamycin, and neomycin.

The macrolide antibiotics are characterized by a lactone ring, a ketone function commonly an α - β unsaturated system, and a deoxyamino sugar containing a dimethyl amino group. Some of these are useful as esters formed by attachment of acyl groups to various hydroxyl groups. Thus the propionyl ester (as the lauryl sulfate salt) and the ethyl carbonate ester, esterified in the hydroxyl group of desosamine, of erythromycin have practical utility.

The polyene antibiotics, having the general structure (CH=CH)_n, also contain large lactone rings, but are set apart from the macrolides both chemically and biologically. They are active against a variety of fungi, including both yeasts and filamentous forms, but are inactive against bacteria or actinomycetes. Of these, amphotericin B, a heptaene polyene, and nystatin, a dienetetraene polyene, have been most useful in the treatment of a variety of fungous diseases (Chap. Thirty-two).

Mechanisms of action.^{65, 66} The marked activity and specificity of the antibiotics has stimulated great interest in the nature of the antimicrobial effects they produce. Sufficient information is now at hand to allow a tentative grouping of these substances with respect to the mechanisms of

their action.

Cell wall synthesis. The penicillins, and a number of other antibiotics including cycloserine, bacitracin, novobiocin, vancomycin, and ristocetin, appear to affect primarily the cell walls of sensitive bacteria. It will be recalled (Chap. Three) that bacterial cell walls are made up of a number of substances which are structurally unique in that they are not found in mammalian cells, e.g., the "unnatural" isomers of glutamic acid and alanine, α - ϵ -diamino pimelic acid, muramic acid, and the teichoic acids. The chemical uniqueness of the cell wall structure of bacteria may contribute in large part to the lack of toxicity of the penicillins, e.g., to the mammalian host.

The susceptibility of the actively growing bacterial cell to penicillin and its relative resistance in the resting stage suggest that an active synthetic process is affected. Further, in the presence of penicillin, actively multiplying cells tend to continue to grow for a time, but do not divide, and may eventually be stripped of cell wall with the formation of protoplasts. Concurrently, uridine diphosphate derivatives of muramic acid and muramic acid peptides accumulate, and the accumulation correlates with the relative antibacterial activity of the several penicillins. On the basis of such observations and other more detailed evidence of the same general nature, it seems clear that a primary effect of penicillin on sensitive bacteria is that of inhibition of cell wall mucopeptide synthesis.

Available evidence indicates that, although the same general consequence is produced by cycloserine, the mechanism differs. Growth inhibition by this antibiotic is reversed by p-alanine. The synthesis of

muramyl peptide by the growing bacterium involves the addition, one by one, of single amino acids to uridine diphosphate-N-acetyl-glucosamine-3-O-lactic ether to give a tripeptide terminating in lysine. The terminal dipeptide, D-alanyl-D-alanine, is then added as a unit. In the presence of cycloserine, there is an accumulation of the muramyl tripeptide. The antibiotic does not prevent the addition of D-alanyl-D-alanine, but competitively inhibits alanine racemase and D-alanyl-D-alanine synthetase. There is not yet sufficient information about the mechanisms of action of the other antibiotics which appear to affect cell wall synthesis.

Permeability. The cyclic peptide antibiotics—the polymyxins, tyrocidin, and gramicidin S—and the polyene antibiotics produce an immediate and rapid leakage of low molecular weight substances, e.g., constituents of the amino acid pool, which is independent of growth of the bacteria in the presence of the antibiotic. The precise mechanisms are as yet quite uncertain and probably are different. Thus the polyenes are antagonized by sterols, and sterols are constituents of fungal cell membranes but not of bacteria, which are resistant to these antibiotics.

Protein synthesis. The antibiotics which inhibit net synthesis of protein in affected bacteria include chloramphenicol, streptomycin (and the similar antibiotics streptothricin, kanamycin, neomycin, viomycin, and paromomycin), the tetracyclines, and puromycin. The last is sufficiently toxic that it has little chemotherapeutic value. The biosynthesis of protein is considered elsewhere (Chap. Five), but it may be summarized here as follows: Amino acids are activated by ATP as aminoacyl adenylates, which in turn react with sRNA. The aminoacyl-sRNA complexes are transferred to determined positions on the mRNA template in association with ribosomes (Chap. Three), and the polypeptide chain is built up by linkage through peptide bonds. The antibiotic activity associated with inhibition of protein synthesis may be considered against this background.

Chloramphenicol does not inhibit the synthesis of DNA and RNA; in fact these syntheses continue in concentrations of the antibiotic which stop protein synthesis, and RNA synthesis may even be stimulated. Studies on cell-free systems have indicated that this antibiotic does not affect the activa-

tion of amino acids, their transfer to sRNA. or the binding of sRNA to ribosomes, but that it does block the transfer of amino acids from xRNA to ribosomes. It combines with ribosomes to produce a complex having a sedimentation constant of 15 S which behaves as loosely coiled polyelectrolyte, like RNA rather than ribosomes, but the nature of the complex remains uncertain. It is also uncertain that protein synthesis is inhibited by preventing the combination of mRNA with the ribosome. It seems to be clearly indicated, though, that inhibition of protein synthesis by this antibiotic is intimately associated with its effects on ribosomes.

Streptomycin affects sensitive bacteria in a variety of ways, including inhibition of the oxidation of certain substrates, breakdown of RNA, and damage to cell membranes, as well as inhibition of protein synthesis. It seems probable that the first two effects are secondary to effects on permeability and protein synthesis, but which of these is secondary to the other is obscure. Studies on protein synthesis have shown that streptomycin is bound to ribosomes, and that the mRNA binding site on the 30 S component is altered so that the information carried by mRNA is misread, with synthesis of abnormal nonfunctional protein. But it is not at all clear how this effect may be related to changes in permeability, reflected as a rapid loss of potassium.

Tetracyclines inhibit adaptive enzyme formation (i.e., protein synthesis) and phosphorylation but not respiration of mitochondria, and the blocking of phosphorylation of adenine nucleotides suggests the possibility of interference with the Krebs cycle. They also function as chelating agents, and their inhibitory effects may be reversed by metal ions. They have been found to inhibit the transfer of amino acids from aminoacylsRNA to ribosome protein, but not the binding of sRNA to ribosomes: such data have been considered to suggest that these antibiotics inhibit the formation of peptide

bonds.

THE APPLICATION OF CHEMOTHERAPEUTIC AGENTS

Since the antimicrobial activity of the chemotherapeutic agents (not only the antibiotics but also sulfonamides and the synthetic compounds such as p-aminosalicylic acid and thiosemicarbazones) is primarily growth-inhibitory, it is assayed by growthinhibition tests. Conversely, the relative sensitivity of kinds and strains of microorganisms is determined by test against standard concentrations of such substances.

Assay of activity. The assay methods are of two general kinds, the tube method and the disc method. In the former, serial dilutions of the substance are prepared in a standard liquid culture medium, and the culture tubes (or flasks) are inoculated with a constant number of bacteria, incubated, and examined for growth. Thus the activity may be measured as the smallest amount of the active substance that prevents growth under the specified conditions. When large numbers of tests are to be carried out, as in the routine testing of bacterial sensitivity. the method is relatively time-consuming. and so is not often used.

The so-called disc method is based on the zone of growth inhibition surrounding a colony of antibiotic-producing microorganisms growing in culture in which the test microorganism is growing as a continuous film on the surface of the agar medium as described earlier. The first such method devised consisted in placing small, sterile, glazed ceramic or glass cylinders vertically on the surface of the uniformly inoculated agar medium and pipetting into them serial dilutions of the substance under test. The activity diffuses outward in the culture medium and, within limits, the activity of the preparation may be determined by comparison with the zone of growth inhibition produced by the standard. Six such cylinders may be appropriately arranged in the usual petri dish culture without overlap of inhibition zones. The standard on which such an assay is based is arbitrarily determined. The activity of penicillin, for example, was originally defined as the Oxford unit, a standard strain of Staphylococcus being used as the test microorganism. This was subsequently replaced by the International Unit, which approximates the Oxford unit; the standard preparation is one of crystalline sodium penicillin G, containing 98.5 per cent of penicillin G. It contains 1670 IU per ml., and the IU is 0.5988 ± 0.5 per cent µg.45 Similarly the IU of streptomycin is arbitrarily defined, but almost equivalent in activity to that of 1 μ g of pure dihydrostreptomycin base,41 and the oxytetracycline standard preparation contains 900 IU per mg.⁴² Similar international standards have been defined for tetracycline⁴³ and for erythromycin.⁴⁴

This kind of assay is not confined to the measurement of the activity of chemotherapeutic substances but has also been applied to other antimicrobial substances such as the quaternary ammonium compounds. In contrast to assays of the phenol coefficient type, it does not depend upon a sterility end point and measures growth-inhibitory rather than lethal activity.

Sensitivity tests. The great bulk of such assays, however, is directed toward the measurement of the sensitivity of microorganisms isolated from disease conditions as a guide to effective chemotherapy. While certain generalizations may be made, viz., gram-positive bacteria are sensitive to penicillin and gram-negative bacteria, with certain exceptions, are not, and the converse relation holds true with streptomycin, too much reliance cannot be placed upon them for two reasons. First, bacteria may become resistant to chemotherapeutic substances (Chap. Seven) so that the sensitivity of a given strain may not be predicted with complete confidence. Second, some kinds of bacteria, such as α -hemolytic streptococci, vary widely from strain to strain in their sensitivity to antibacterial chemotherapeutic agents. Testing for sensitivity of isolates has, then, become a routine diagnostic adjunct.

The sensitivity spectrum so determined depends upon the context from which it is taken. The usual spectrum of a given chemotherapeutic substance is commonly derived from stock cultures of bacteria, but that found with isolates from infectious processes may differ, usually in that resistant strains of bacteria "normally" sensitive to a given agent may be found. In a general way, such a shift is most pronounced in isolates from populations of hospitalized persons, and tends to be related to the kinds of chemotherapeutic agents used and the extent to which they are used. The utility of a given chemotherapeutic substance thus depends upon a number of factors, and the spectrum of its activity is more realistically given by the proportions of bacterial strains found to be sufficiently sensitive to it so that it has utility as a therapeutic agent. An illustration of such a practical spectrum of activity is given in the accompanying table.

The diagnostic sensitivity test. The sensitivity test applied for this purpose is considerably simplified by the use of filter paper discs impregnated with appropriate concentrations of the chemotherapeutic substances. This kind of test is recommended as an international standard,113 and for routine tests with pathogenic bacteria (excluding tubercle bacilli) the following antibiotics should be used: erythromycin, novobiocin, vancomycin, bacitracin, penicillin, tetracycline, chloramphenicol, neomycin, streptomycin, and polymyxin. The discs are placed upon the surface of the agar culture medium uniformly inoculated with the test bacterium. There are many variations on this scheme, including cogwheel-shaped pieces of filter paper having the projections impregnated with different substances, circular pieces with impregnated projections toward the center, etc. In any case, two concentrations of the antibacterial substances are usually used, a "high" and a "low" concentration. For example, the concentrations of penicillin are 10 and 1.5 units, of tetracycline 25 and 4 units, erythromycin 10 and 1 unit, streptomycin 100 and 10 μ g, etc. The "high" concentration is intended to approximate the maximum blood levels of the substance attainable, but this is not always true. For instance, for technical reasons, sensitivity to streptomycin for therapeutic purposes is best shown by the indicated concentrations, although in this case the blood level attained is more nearly 10 μ g than 100 μ g because of toxicity.

After incubation the test is read as the diameter in millimeters of the zones of growth inhibition, but judgment must be used since the size of the zone of inhibition is also a function of the rate of diffusion of the activity into the culture medium. A high degree of sensitivity, for instance, is indicated by a maximal zone of inhibition around the "low" concentration even though that around the "high" concentration may not be larger because of the diffusion factor. This method of assay of bacterial sensitivity is widely applied and gives remarkably consistent results in view of its relative crudity.

Secondary infections. 63 The microbial flora of man and other animals is diverse, and when an antimicrobial agent is administered for therapeutic purposes, there is an inevitable side effect on the normal flora due to the selective toxicity of the agent.

The state of the s	-												

*Organisms are from the first 400 tested each month from July 1966 through June 1967 in the Clinical Microbiology Laboratory of the University of Chicago Hospitals and Clinics. The percentages shown here are of organisms considered sensitive or moderately sensitive, with zones of inhibition of 18 mm. or more in

diameter (11 mm. for cephalothin) with the high concentrations in the disc test. These data are not necessarily characteristic of nonhospitalized infections, those of other hospitals, or of this hospital at other times. (Compiled by Dr. R. S. Benham and Miss Isabelle Havens.)

In the normal individual the character of the microbial flora is determined by many factors, and of these a significant element is the interrelationships of the microorganisms present in, for example, the large bowel. In this case, in addition to the quantitatively predominant coliforms, other gramnegative bacilli such as Proteus, sporulating anaerobes such as Cl. welchii, α-hemolytic streptococci or enterococci, staphylococci, fungi such as yeasts, and filamentous forms such as Candida albicans are present in small proportion. When an antimicrobial substance is introduced, this flora changes in character with the emergence of minority forms that, when present in greatly increased proportions, assume some degree of pathogenicity. This effect is most commonly observed following oral administration of broad-spectrum antibiotics but may also occur when other antimicrobial substances and other routes of administration are used.

Thus secondary infections may occur which are quite unrelated to the disease condition for which therapy was initiated. There are three kinds of more common consequences. First moniliasis or candidiasis (Chap. Thirty-two) may develop by uninhibited, or possibly stimulated, proliferation of the fungus C. albicans with consequences ranging from, for instance, local irritation in the bowel, anus, or vagina, to a generalized, sometimes fatal, infection, especially in young children. Second, with selective inhibition of other components of the intestinal flora, staphylococci, often resistant forms, may become predominant to produce diarrheal disease and occasionally fatal staphylococcal toxemia. Third, when the growth of coliforms and enterococci is markedly depressed, forms such as Proteus and Pseudomonas may grow freely and invade the tissues to produce infections of the kidneys or urinary bladder. Still other effects may be produced by intensive antibiotic therapy. For example, the bacterial flora of the mouth and throat often become predominantly coliform in character, with coliform throat cultures not uncommonly encountered in the diagnostic laboratory, and it is believed by some that some strains of coliform bacilli, especially hemolytic forms, may produce inflammatory changes in the throat.

The overall effect of the general use of chemotherapeutic agents is illustrated in

compiled data from the Boston City Hospital from 1935 to 1957.²² Staphylococcal infections of the blood and meninges increased greatly, and there has been a coincident enormous increase in bacteremia and meningitis due to gram-negative bacilli, viz., Proteus, Klebsiella (coliform), and Pseudomonas. The mortality from bacteremia decreased from 1935 to 1947, but thereafter rose rapidly until by 1957 it was 50 per cent higher than in 1935.

Combined therapy.⁶ In view of the selective action of antimicrobial substances, their administration in combination is inevitable, both to broaden the antimicrobial activity of the preparation in the absence of precise diagnosis of the etiological agent in treatment of mixed infections, and to minimize the secondary infections occurring during intensive therapy described above and to reduce the probability of the development of resistance by the microorganism (Chap. Seven).

Various combinations, sometimes mixtures and sometimes compounds, have been prepared. Among the mixtures, the combination of streptomycin or isoniazid with p-aminosalicylic acid is almost routinely used in the treatment of tuberculosis; this is something of a unique situation in that the disease requires prolonged therapy which favors the development of bacterial resistance, and because of the facility with which the bacilli become resistant to streptomycin and, to lesser extent, to isoniazid. Other combinations include the admixture of antifungal substances such as candicidin, fungicidin, or undecylenic acid with the broad-spectrum antibiotics, especially the tetracyclines, to minimize fungal overgrowth during therapy, and various combinations of antibiotics such as tetracycline plus nystatin (Mysteclin) or plus oleandomycin (Sigmamycin, Signemycin).

Compounds of antibacterial substances include: streptomycyclidene isonicotinyl hydrazide sulfate (Streptohydrazid); Streptobine, a stable salt containing 48 per cent dihydrostreptomycin, 34 per cent isoniazid, and 18 per cent pyruvic acid; Hiconstarch, a polymer prepared from periodate-oxidized potato starch by condensation with equimolar proportions of isoniazid and p-aminobenzalthiosemicarbazone; a compound of isoniazid and p-aminosalicylic acid (Pasiniazide, Dipasic); isonicotinyl hydrazone

benzaldehyde metasulfonic acid (G605, Sulfoniazide); etc. The value of such preparations is not established.

Synergism and antagonism. Contrary to what might be supposed, the effect of combination of two substances demonstrable with a single species of microorganism susceptible to both is not necessarily an additive one. This phenomenon has been studied by a number of workers, especially by Jawetz and his colleagues⁴⁹ and by Klein and his coworkers.⁶⁰ Klein has summarized the kinds of effect produced by drug combinations both in vitro and in vivo as follows:

- (1) A synergistic effect may be defined as that in which the activity of two drugs in combination is greater than that obtained by doubling the concentration of either alone.
- (2) An additive effect is that in which the antibacterial activity of the combination is greater than that of either drug alone, but less than that obtained by doubling the concentration of either.
- (3) The effect is one of interference when the antibacterial activity of the combined drugs is not greater than that of either drug alone.
- (4) Two drugs are said to be antagonistic when the antibacterial activity of the combination is less than that obtained with either drug alone.

Effects falling into one or the other of the above categories have been observed with mixtures of sulfonamides with antibiotics and with mixtures of different antibiotics but are sometimes difficult to interpret. For example, one of the most widely tested combinations is that of streptomycin with p-aminosalicylic acid in the therapy of tuberculosis; this combination appears to be invariably synergistic. The combination of penicillin and sulfonamides, however, is initially antagonistic, but this is transitory and the effect eventually becomes synergistic.

Jawetz has generalized the interrelationships among the antibiotics by placing them into two groups: the first is made up of penicillin, streptomycin, bacitracin, and neomycin; and the second of Aureomycin, chloramphenicol, and Terramycin. He has found that members of the first group are often synergistic with each other and never antagonistic, while pairs of the second group show only an additive effect. The consequence of combining antimicrobial substances of different groups is variable and dependent upon the sensitivity of the microorganism to the drug in the first group; if it is highly sensitive, the second antimicrobial substance will interfere, but if it is relatively resistant the combination may be synergistic. He has suggested the following possible explanations:

- (1) The two antimicrobial substances combine chemically to give a more active compound.
- (2) One antimicrobial substance is effective on those bacteria that are resistant to the other.
- (3) One antimicrobial substance affects actively multiplying bacteria and the other viable but nonreproducing microorganisms.
- (4) One antimicrobial substance potentiates the other indirectly, for example, by decreasing the permeability of the cell wall.
- (5) The combination of antimicrobial substances simultaneously blocks more than one metabolic pathway, preventing a facile shift by the microorganism in the presence of a single antimicrobial substance.

Of these, the first is quite unlikely on the basis of present evidence. The second is probably the explanation of the PAS-streptomycin synergism in the treatment of tuberculosis. The third is probably the explanation of the behavior of sulfonamidepenicillin combinations; *i.e.*, the sulfonamides are primarily bacteriostatic and exert an immediate effect, while penicillin is effective only on actively multiplying microorganisms. Evidence has been presented in support of the fifth possibility in the case of penicillin-streptomycin and Terramycin-bacitracin combinations.

Klein has taken the view, and supported it by strong experimental evidence, that synergism occurs only when the microorganism tends to become resistant and is related to the inhibition by the second drug of resistant microorganisms surviving the action of the first. It follows that when resistance does not develop with some facility, synergism commonly does not occur, and some degree of antagonism may be observed. The consequences of combining drugs are dependent upon the drugs, upon the strain of microorganism, and upon the conditions under which the organism is subjected to the action of the drugs. On the basis of present information, then, the activity of combinations of drugs is more or less unpredictable, and this is in accord with the observations of many workers. The considerable uncertainty as to the indication for combined therapy may, then, be resolved by the requirement that the microorganism show a significant increase

in resistance to the chemotherapeutic agent. either promptly in acute disease or ultimately in chronic infections. Obviously, each of the combined drugs must have some activity against the microorganism, and they must differ from one another in their modes of action in such a way that cross-resistance does not develop. It is quite clear that as vet no rationale has been formulated for combined therapy of infections with microorganisms that do not become resistant with reasonable facility, e.g., infections with pneumococci, Str. pyogenes, and others, and the fundamental distinction must be made between infections in which resistance is and is not a factor.

Other applications. A number of the antimicrobial substances have useful applications other than in the treatment of infectious disease. The most important of these are the use of antibiotics as feed supplements and in food preservation. In the first instance it is established that the inclusion of small amounts (2 to 50 ppm) of antibiotics in animal feeds results in more rapid growth of domestic meat animals, increased hatchability of fertile eggs, and other indications of an enhanced nutrition. and such supplemented feeds are widely used. The nature of this effect is not clear.97 It is thought by some to be a result of increased vitamin synthesis by the intestinal flora. The traces of antibiotics persisting in foods of such animal origin are apparently not significant, though there may be sufficient activity in eggs to prevent the growth of bacteria for experimental purposes in the embryonated hen's egg.

The treatment of freshly dressed meats such as fish and fowl in dilute solutions of broad-spectrum antibiotics has a preservative effect such that they stay fresh appreciably longer, and these substances may well have broad application in food preservation.16, 20, 114 Chlortetracycline has been approved for this purpose in a concentration of 7 ppm; it is destroyed when the food is cooked.

MICROBIAL VARIATION AND GENETICS

Prior to the development of methods of isolation of bacteria in pure culture, i.e., as clones, and the study of such isolates, these microorganisms were regarded as closely related or identical but of highly variable morphology. This view reached its zenith in 1877 with Nägeli, who postulated but a single species to which all bacteria belonged. This early concept of extreme pleomorphism was almost, but not quite, shattered by the study of bacteria in pure culture and the consequent development of a strict monomorphism by Koch and others which admitted substantially no change in the characteristics of bacteria in pure culture. It subsequently became clear that a more realistic view is a compromise between these two extremes, i.e., bacteria in pure culture have a continuing identity which is subject to variation within limits, although as yet these limits cannot be rigidly defined. Further, as the viruses have become better known, it has become evident that these forms too are subject to substantially the same kind of variability as the bacteria.

In a consideration of this aspect of microorganisms, it is essential to have clearly understood the reference point, or norm, from which deviations occur. Such a norm is difficult, if not impossible, to define in any absolute way. There is a tendency to assume as the "normal" the character of a microorganism occurring under conditions of man's devising, such as the properties of a microorganism growing or grown under laboratory conditions. One of the most obvious examples of the potential fallacy in such an assumption is the varied morphology of the symbiotic nitrogen-fixing bacteria of the genus Rhizobium between the regular,

rod-shaped form occurring on laboratory culture mediums and the so-called bizarre forms observed in its natural habitat, the nodules of leguminous plants, which is illustrated in the accompanying figure. In a very real sense there is no "normal," but rather many base lines which can be defined only in the context of the particular conditions under which the microorganisms have been grown and, to complicate matters further, often its past history. Any deviation, then, must be defined in terms of the reference point arbitrarily taken.

THE "UNIQUE" FEATURES OF MICROORGANISMS

In many respects microorganisms are seemingly unique among living things, and in a general sense this "uniqueness" is of three kinds. One is a consequence of their extremely small size, which has been touched upon earlier in relation to the morphology and growth of these forms. The accompanying simplicity of structure necessitates the use of differential criteria of a more subtle kind than those of comparative anatomy applicable to higher forms, viz., physiological and immunological properties. It is obvious that when a microorganism is so characterized, variability consists of deviation from some base line in these respects. Because such criteria are not usually applicable to higher forms, the impression is produced that the microorganisms are somehow "different." This is clearly fallacious as indicated by studies on the physiological genetics of higher forms and by the parallelism between the immunological relation of, for example,

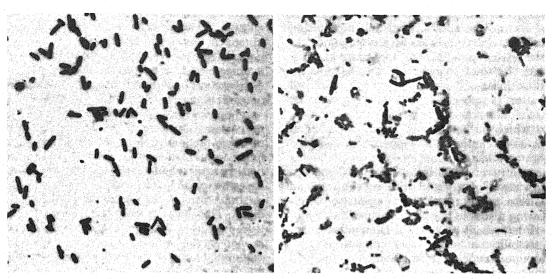

Figure 49. The morphology of Rhizobium. Left, a smear from a pure culture on laboratory mediums; note the regularity of the "normal" bacillary morphology. Right, smear from a clover root nodule showing swollen, branched, and coccoid forms, the so-called bacteroides. Fuchsin; × 1050.

the serum proteins of mammals and their phylogenetic relationships based upon a comparative anatomy (Chap. Thirteen).

The microorganisms share with other cells the essentially abstract environment in which factors such as exaggerated forces of surface tension and the predominance of interfacial phenomena at near-molecular or macromolecular dimensions play a large part. They differ from the differentiated cells of higher forms, not only in being smaller, but more significantly in being independent, complete units. As such they are not protected from marked variation in the immediate environment by the other components of a multicellular structure or by extensions of the structure such as regulatory mechanisms of homeostasis present, for example, in the mammal. Thus the directive mechanisms that maintain the integrity of the microorganism are not far removed from a variable external environment, and it might be anticipated that their functioning could be altered by extracellular influences. Such differences between microorganisms and other living things are, of course, a matter of degree rather than kind.

A second kind of seeming uniqueness derives from the extremely rapid rate of reproduction of the microorganisms. Whether it is a matter of environmental selection of the fittest from a mass of pre-existing heterogeneous individuals or of mutants conforming more closely to the requirements of a particular environment, variant forms appear

relatively rapidly. This might be taken to suggest that the microorganisms are unusually facile in this respect or, from another point of view, are relatively unstable with respect to at least certain of their characteristics. When the period of 30 years, generally taken to represent a human generation, is contrasted with that of 20 minutes for a rapidly growing microorganism, it becomes clear that the ready adaptability of microorganisms may be accounted for in large part by rates of reproduction. For example, mutation rates of bacteria are of the same general order as those demonstrable in more complex forms such as Drosophila, even though they appear much more rapidly in terms of elapsed time.

Finally, in contrast to many higher forms, the individual microorganism is not characterized except in a limited way, as with respect to size and shape of the individual cell. The statement that Bacillus X ferments such-and-such a sugar is not literally true. More accurately, it should be said that the sugar is fermented in the presence of a mass of many millions or hundreds of millions of the microorganism. This is not quibbling, but is rather, a recognition of the limitations imposed by the practical necessity for studying microorganisms as large populations, and recognition of this fact is of primary importance to an understanding of the mechanisms operative in microbial variation.

The properties of microorganisms must, then, be studied in terms of population biology. In the population, the individuality of its members is merged and disappears, and the characteristics of a population, expressed as statistics, are both more and less than the total character of the discrete entities that make it up. This is often a difficult matter to appreciate, for man reacts as an individual and conceives of the population to which he belongs as largely a matter of his own relation to it. Tippett has suggested that arriving at a concept of a population as an entity in itself is analogous to the appreciation of a fugue with its contrapuntal pattern as contrasted with the ease of following a simple harmony or tune.

For present purposes it is significant that variability is an inherent characteristic of populations; in fact, if each of its component entities were identical with all the others, it would lack such distinguishing characteristics as, for example, mean or median size. So far as is known, living organisms are seldom if ever precisely identical, and a

microbial population, such as a bacterial culture, is no exception but is seemingly homogeneous because it is studied as a population and individual differences are averaged out. Microbial variation is, then, a change in population character from which one infers causality on an individual basis.

It will be clear from the foregoing that microorganisms are not unique in the sense of being fundamentally different from other living forms. One may expect, therefore, to find that microbial variability has the same bases as variability of higher forms, although in some cases its expression may appear to differ. This has not only been found to be true, but, as will appear, study of variation in microorganisms has both broadened and pinpointed genetic mechanisms to an extent not possible in the study of higher organisms.

Here variation will be considered under two general heads, the kinds of variation observed, and the mechanisms operative in such variation.

Observed Variations of Microorganisms

Microorganisms have been found to vary, sometimes widely, in all the characteristics made use of in their differentiation and identification. These include morphology, both macroscopic and microscopic; physiological properties, including ability to produce disease; and immunological character. Changes may appear suddenly, i.e., in a single subculture, or they may become apparent only gradually, as in aged cultures or over many transplants or animal passages and some hundreds of generations. The rapidity of appearance, however, cannot be taken to have fundamental significance and, in fact, in many instances is subject to experimental manipulation. Variants may appear apparently spontaneously or may be seemingly induced, as by making the culture medium mildly and specifically toxic by the inclusion of lithium chloride, antiserum. antibacterial substances, and the like, or by making it selective so that the expected variant is given enhanced survival value as, for example, by including a sugar in the medium in attempts to isolate fermenting variants of a nonfermenting parent strain. In fact, in practice the single most potent factor in the demonstration of microbial variants is the selective nature of the environment, which may be either inadvertent

or planned. Without this factor the relatively rare variant or mutant cannot achieve the numerical status necessary to give an observable change in the population of microorganisms.

In any case, the variation is observed as a population characteristic in that the variant character of the individual cell is found in subculture, and the inference regarding the individual cell rests upon the assumption that the variant character breeds true for at least this long.

MORPHOLOGICAL VARIATION

Variation in the morphology of bacteria may be considered under two general heads: colonial morphology or that of masses of cells, and the morphology of individual bacterial cells.

of bacterial dissociation. A remarkable type of bacterial variation, whose most obvious outward manifestation is a change in the type of colony formed on semisolid mediums, was observed by Baerthlein in Germany (1918), Arkwright in England (1921), and de Kruif in the United States (1921). The phenomenon was termed by de Kruif

bacterial or microbic dissociation, a term which has, in spite of certain undesirable features, been generally adopted.

Colonial morphology. The ordinary laboratory culture, particularly old broth cultures, when plated out on an agar medium develops into two kinds of colonies: one is smooth (S), round, convex, and shining; the other is rough (R), irregular, flattened, and wrinkled. In addition to these obviously different extreme colony types, all degrees of intermediate (SR and RS) types may usually be found. The transformation of the S form, usually regarded as the "normal," into the R type is, as indicated by the presence of intermediate types, probably a gradual process. The smooth form of the great majority of bacteria, while breeding true for a number of test tube generations, shows a constant tendency to change to the rough type; one of the consequences of this tendency is that most stock laboratory cultures contain a large proportion of roughs, and sometimes such cultures are completely lacking in smooth forms.

A third kind of colony, the M or mucoid, is also commonly recognized, characterized by a slimy, mucus-like consistency and appearance. The mucoid character may be associated with the S or R colonial types to give mixed or intermediate forms, but it is thought by many that S is intermediate between M and R and that the succession is $M \rightleftharpoons S \rightleftharpoons R$. In individual cases other

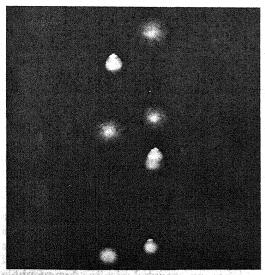

Figure 50. Smooth and rough colonies of Salmonella typhi. Culture on nutrient agar inoculated from an old broth culture, × 3.

colonial forms may be observed; the hemolytic streptococci, for example, occur in a form designated "matt" by Todd and the British workers which has a ground-glass appearance when viewed by reflected light. Still another form, the dwarf colony or D type, may be produced by experimental manipulation and is sometimes isolated from the natural habitat of the microorganisms. Colonial differences, often very slight in character but frequently associated with virulence and other physiological properties, are apparent when the culture is examined under low magnification by oblique, transmitted light as described by Henry.⁴⁴

The transformation of S to R, though occurring in ordinary cultures, may be hastened by a number of procedures, such as the inclusion of lithium chloride or anti-S immune serum in the medium in which the organisms are cultured. Smooth cultures lysed by bacteriophage give rise when incubated to a secondary growth which often consists entirely of R forms. The change from R to S is considerably more difficult, and the rough forms show little tendency to revert under ordinary cultural conditions. The reversal may, however, be accomplished in most cases, one of the most effective methods being the cultivation of the R form in the presence of anti-R immune serum. Reversion of the R type may also be brought about by animal passage.

Properties of S and R variants. The bacteria which make up the smooth and rough colonies differ from one another in a number of characteristics, some of which are usually regarded as of deep-seated biological significance.

The distinctions between the S and R types given in the accompanying tabular form represent a generalization to which there are a number of exceptions. For example, what is usually regarded as the "normal" form of the anthrax bacillus is the rough form, and in this case the organism is virulent in the rough form but avirulent in the smooth form. Similarly, the "normal" virulent form of the hemolytic streptococci is finely granular rather than smooth, and the avirulent form which arises from it has lost its typespecific antigen but is smoother than the virulent form. In spite of these and other exceptions, the differences noted above hold true in general.

Cellular morphology. Closer inquiry into the differences between S and R bacterial types indicates that the relation between

Contrasting Properties of S and R Varieties

S TYPE

R TYPE

Colony usually smooth and viscous Pathogenic forms usually virulent Forms stable suspensions in salt solution

Encapsulated forms have capsules Antigenically "complete"

Colony often dry and granular and may be larger Pathogenic forms often relatively avirulent Spontaneously aggregates and settles out in granular deposit from suspension in salt solution Capsules diminished or absent Often show loss of antigens, sometimes with the appearance of "new" antigens

colony form and certain other characters is not in the nature of a casual correlation but rather the result of an intimate association. The association between capsules and virulence has been pointed out previously, as has been the role of the capsule in giving the colony of encapsulated bacteria in a slimy, viscous consistency. It is not unreasonable to expect, then, that a bacterium which lacks a capsule is also avirulent, or relatively so, and that its colonies will be dry and possibly wrinkled in appearance. The loss of a capsule likewise alters the nature of the bacterial surface: the absence of carbohydrate material allows the lipids present in the cell membrane to determine its character; in consequence, it becomes hydrophobic rather than hydrophilic, and the organisms tend to clump and settle out of salt solution or the nutrient broth of a culture. The granular consistency of many of the rough colony types is accounted for, in part, by postfission movements of the cells. The smooth forms of some of the intestinal bacilli separate after fission and slip to lie side by side with one another. The cells of the rough forms, on the other hand, tend to remain attached after fission with the formation of chains which bend at sharp angles here and there. The development of bizarre shapes by some of the rough forms may possibly be a result of the absence of capsular material and change in the nature of the cell surface. The nature of the association between roughness and reduced biochemical activity is unknown.

Induction of dissociation. Experimentally, the inclusion of antiserum to the S or R form will frequently result in the appearance of the other form; the occurrence of avirulent R forms of pathogenic microorganisms isolated from chronic carriers of the infection is presumed to be a consequence of the effect of antibody developed to the virulent S form.

Most often the change, especially the $S \rightarrow R$, occurs in old liquid cultures and is an effect of accumulation of metabolites. The role of metabolites in the $S \rightarrow R$ dissociation has been strikingly illustrated by the studies of Braun and his colleagues^{24, 36} on Brucella. Smooth strains cultured in synthetic medium containing asparagin as the sole source of nitrogen multiply in the usual way, but after some days of incubation are replaced by R forms. The occurrence of R forms coincides with the accumulation of d-alanine, which is specifically toxic to the S but not the R form. The $S \rightarrow R$ shift is prevented by including sodium pyrophosphate in the medium. This substance forms complexes with manganese and magnesium, trace elements that act as catalysts in alanine formation; the effect of pyrophosphate is in turn antagonized by the addition of manganese or magnesium. Smooth virulent forms, differing from the original smooth type in that they are resistant to alanine, may also be isolated. It is of considerable significance that the effects of amino acids may occur in vivo also. For example, in the case of Salmonella typhimurium, virulence for the mouse was greatly enhanced by administration of threonine to the animals; a more highly virulent, threonine-resistant variant, occurring as less than 1 per cent of the original inoculum, was selected in vivo.78

Variation in cell structures. As indicated above, colonial morphology is in part a function of the morphology of the individual cells making up the colony, and one of the most important factors in the differential morphology of the S and R variants is the occurrence of hydrophilic polysaccharide on the surface of the cell. As pointed out elsewhere, this frequently takes the form of a layer or morphologically demonstrable capsule on the outer surface of the cell.

Capsules. Capsule formation or, from the

physiological point of view, the synthesis of capsular substance usually of polysaccharide but sometimes of polypeptide nature, is very common among the bacteria, but a morphologically demonstrable capsule is not always apparent. Capsule formation is dependent in large part on the environment, and the most favorable medium in the case of pathogenic bacteria in which capsule formation is associated with virulence is the body of the susceptible animal. The anthrax bacillus forms a heavy capsule in the infected animal, but there is little or no evidence of a capsule when the bacilli are cultivated on laboratory mediums. The pneumococcus, likewise heavily encapsulated in the infected animal, also forms a capsule in artificial mediums, but the capsule is best developed when the medium is enriched with blood or serum and carbohydrate. Among the pathogenic forms. capsule formation tends to diminish with continued cultivation on artificial mediums. probably because these furnish a somewhat less than optimal environment, and is restored by animal passage of the bacteria.

The heavily encapsulated saprophytic bacteria, such as the dextran- and levulanforming cocci of the genus Leuconostoc, show no tendency to loss of capsule formation in culture provided that carbohydrate is supplied, and it seems probable that the artificial medium is more nearly optimal than it is in the case of the more fastidious pathogenic bacteria. In general, then, capsule formation is determined in large part by the environment, may be a quantitative matter, and is reversible.

Capsule formation may be specifically inhibited, however, the most effective means being the inclusion of antiserum to the capsular material in the culture medium. The loss of capsule formation under such circumstances, or when it is relatively complete by thorough prolonged culture on artificial mediums, results in the S-R dissociation, and the lack of a capsule is characteristic of the rough variant. As indicated above, this loss is also reversible, though frequently only with considerable difficulty. Whether it is to be regarded as basically different from a gradual diminution in the amounts of capsular substance synthesized through continued cultivation in a less than optimal environment is not clear.

Flagella. The occurrence of flagella on motile bacteria is also subject to variation. There appears to be little or no variation with respect to numbers or position of flagella, but

their presence or absence is variable. Nonmotile variants of motile bacteria are occasionally, though not commonly, observed, and these appear to be stable forms with little tendency to reversion to the motile form. In the case of very actively motile bacteria such as Proteus, colonial morphology is affected by motility in that the motile bacteria "swarm" and the growth spreads in a thin film over the surface of an agar medium, while the nonmotile variants form discrete colonies.

The formation of flagella is subject to environmental influence also. Actively motile species kept in stock culture on laboratory mediums tend to lose their motility, and potentially motile bacteria may be motile when cultivated at one temperature but not at another. The inclusion of antibacterial substances such as phenol in the medium in toxic but nonlethal concentrations inhibits the formation of flagella by bacilli of the Salmonella group; in fact, one method of obtaining these forms free from flagella and the antigenic substances associated with them is culture on nutrient agar containing 0.1 per cent phenol.

Spores. The spore is a consequence of the aggregation of cell substance within a spore case during spore formation. It is this process rather than the formation of a structure of the vegetative cell that is subject to variation. Like capsule formation, it is essentially a physiological process but with morphological consequences. Spore formation is affected by environmental factors, and asporogenous variants which breed true also occur. In the case of the anthrax bacillus, for example, spores are formed only when the bacteria have access to free oxygen: only vegetative forms are found in the infected animal until the bacilli are exposed to air by tissue decomposition or autopsy and then spore formation occurs. Similarly, spores are formed most rapidly at 32° C., less so at 37° C., and not at all when the culture is incubated at 42° C. The inhibition of spore formation by the anthrax bacillus by high temperatures is a temporary one in that when the temperature of incubation is reduced spore formation again occurs, but if cultures are maintained at 42° C. for many transfers the ability to form spores is apparently permanently lost. In general, however, spore formation is a relatively stable character.

L forms. 57 A kind of variation known as

L variation was first observed by Kleineberger in cultures of Streptobacillus moniliformis (one of the causative agents of rat-bite fever) and subsequently by other workers, especially Dienes, in cultures of a variety of bacteria. The bacteria become more transparent and stain with difficulty or form granules which unite and grow into the amorphous bodies of variable size known as L bodies. These bodies may multiply or give rise to bacterial cells morphologically indistinguishable from the parent strain.

The significance of these variants is uncertain. In morphology they are similar to the pleuropneumonia microorganisms (Chap. Twenty-seven) and appear to be etiologically related to polyarthritis of rats. Whether or not the L bodies are variants of common bacteria and have more than a superficial relation to the pleuropneumonia organisms is uncertain. It is also possible that these bodies represent naturally occurring protoplasts of greater stability than those prepared by enzymatic digestion of the cell wall (Chap. Three); if so, they could be regarded as bacterial variants which are unable to form a complete cell wall structure. 63, 108, 111

Aberrant forms. The occurrence of aberrant or "abnormal" forms of bacteria, differing from the presumably normal morphology of recent isolates and cultures on favorable mediums, is commonly observed. In the earlier literature these are called involution forms and regarded as primarily degenerative in character. While this term is applicable in some cases, it is not necessarily appropriate in all, for some kinds of bacteria show varied morphology as a rule rather than an exception.

The tendency to varied morphology is in part an effect of the environment on the cell and in part a function of the relative rigidity of the cell structure. For example, a transitory alteration in cell shape may be produced by culture of bacteria in toxic, but not lethal, concentrations of substances such as NaCl or certain antibiotics. The distortions produced in the first instance are probably in large part an osmotic effect, and in the second seem to be a consequence of inhibition of processes of cell division while synthesis of intracellular substances continues, giving rise to swollen forms. Or, the inclusion of surface tension depressants in the culture medium frequently results in the growth of bacilli in the form of long filaments and

Figure 51. Involutional forms of the typhoid bacillus. Note the filamentous forms and elongated rods mixed with the typical forms. What appear to be buds on the filament are probably adjacent cells. The poor resolution at these high magnifications is apparent. Fuchsin; × 3500.

similar phenomena. Such aberrant forms are usually viable and on subculture produce normal progeny.

Bizarre forms are also commonly observed in old cultures, particularly in liquid mediums. This is probably a consequence of the presence of relatively large numbers of dead and dying cells and possibly also of the toxic effects of accumulated products of metabolism. When the bacterial cell is dead or dving, its structure begins to break down with autolytic changes. The protoplasm becomes granular and may escape into the surrounding medium, coccoid forms of bacilli and other swollen forms result from the breakdown of the osmotic barrier, etc. For example, the pneumococcus produces peroxide as a terminal product of respiration, but no catalase, so that peroxide accumulates to lethal concentrations, killing the cells. These bacteria contain intracellular proteases, and autolytic changes set in rapidly. One of the first indications of this is a loss of the ability to retain the Gram stain, and even in 24-hour cultures many cells are found to be gram-negative. Similarly, the cholera vibrio is a fragile cell and may be broken up mechanically more readily than most other bacteria; it also contains a powerful intracellular protease; and it is not surprising that it is notorious for its

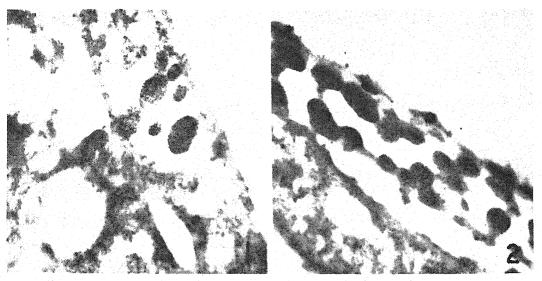

Figure 52. The varying morphological types of feline pneumonitis virus during one-step growth in chorioallantoic ectoderm. Left, the ovoid granulated forms occurring at 15 hours, shown at point 1 on the growth curve in Figure 53. Right, the smaller forms at 20 hours, at point 2 on the growth curve. Electron micrographs, × 15,000. (Litwin.)

morphological variability. Such cells are often dead, in that they do not reproduce on subculture and may be regarded as involution forms.

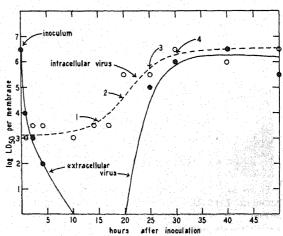

Still other bacteria, notably forms such as Bacteroides and the pleuropneumonia organisms referred to above, seem to be so fragile in structure that they do not occur as a single or predominant morphological type. The Bacteroides are rod-shaped but occur in filamentous and other varied forms, while the pleuropneumonia organisms have a widely varied morphology, including coccoid forms, symplastic masses, and ring forms. Such varied morphology under standard

conditions of culture is, however, the exception, and the great majority of true bacteria, or Eubacteriales, are remarkably constant in this respect.

Microbial life cycles. The occurrence of morphological variation among the bacteria inevitably raises the question of whether morphological variants are random events or have a deeper significance as expressions of cyclical events in the life history of the microorganism.

There is no doubt that simple sequential developmental changes expressed morphologically occur. Obvious examples are the spore-vegetative cell sequence occurring

Figure 53. One-cycle growth curve of feline pneumonitis virus in chorioallantoic ectoderm. The dotted line represents intracellular virus, and the solid line that occurring free. The points labeled 1, 2, 3, and 4 on the intracellular virus growth curve are the stages in the cyclic development of the virus illustrated in Figures 52 and 54. (Litwin.)

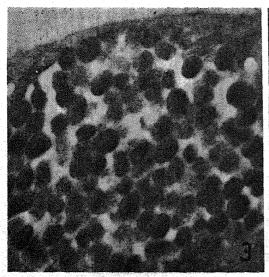

during the growth of spore-forming bacteria, the sequence of morphological types occurring during the growth of a culture and designated cytomorphosis, and the successive zoogleal and monad or swarmer stages of Nitrobacter. Such sequential changes can hardly be taken as expressions of life cyles such as, for example, that of Plasmodium.

The evidence for the occurrence of bacterial cyclogenies is substantially a matter of the observation of cells of varied morphology, in old cultures or similar unfavorable circumstances, and their arrangement in an order that may be taken to represent a sequential relation. The relatively constant morphology of most kinds of bacteria under defined conditions of culture thus becomes but one stage in the life cycle of the bacterium which is maintained to the exclusion of other stages by the environment. The fallacy lies in the arrangement of morphological variants, for it is necessarily subjective rather than objective, and the evidence is less than unequivocal. The possibility of the occurrence of successive developmental stages is not, of course, eliminated, but in any consideration of this kind it must be kept in mind that the organization of the microbial cell is largely on, at most, a macromolecular level, and variation need not have morphological expression. In fact, the great bulk of variations are physiological (see below) and are only rarely associated with morphological changes.

Virus replication cycles. As indicated elsewhere (Chap. Four), replication of the viruses and virus-like agents is characterized by the occurrence in time sequence of successive, differentiable stages. For the most part these stages are separable by immunological and infectivity criteria, and, with rare exceptions, notably the protein head structure of incomplete coliphage, these stages have no morphological counterparts.

Among certain of the larger viruses, however, varied morphology of the virus particle may be observed. The differentiation of the intracellular matrix or inclusion body into particles of poxvirus, heterogeneous with respect to the amount and distribution of electron-dense, presumably nucleic acid, material within the particle has been described elsewhere (Chap. Four). These forms occur admixed within the host cell and, while they may be arranged in an order, the arrangement is as yet arbitrary rather than determined by time or other objective factor.

Members of the psittacosis-lymphogranuloma group have been studied in most detail in this respect, for it was apparent quite early that morphologically different particles occur

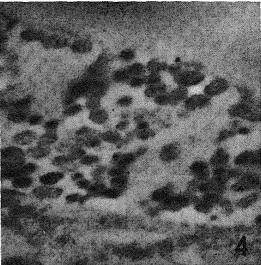

Figure 54. The varying morphological types of feline pneumonitis virus during one-step growth in chorioallantoic ectoderm. Left, the smaller forms have increased in number, corresponding to point 3 on the growth curve shown in Figure 53. Right, mature forms occurring at the end of the growth cycle at 30 hours and showing two morphological types, the smaller dense-centered bodies and the larger granulated forms. Electron micrographs, × 15,000. (Litwin.)

during the course of the reproductive cycle. Their occurrence in an orderly sequence was suggested by studies with the light microscope, 112 and subsequently they were more precisely defined by electron micrography. The growth cycle of feline pneumonitis microorganism in ectodermal cells of the chorioallantois of the embryonated hen's egg is completed in about 30 hours.64 By 15 hours the spherical elementary body, about 200 m μ in diameter, has increased in size to 500-700 m μ and contains an increased amount of electron-dense material: at this point the growth cycle corresponds to the lag phase of bacterial growth. At 20 hours the bodies are somewhat smaller, 500 mμ, somewhat increased in numbers, and the vesicle within which they are contained in the host cell is larger. By 25 hours growth is exponential, the bodies are transitional in size, ranging from 200 to 500 m μ , and the vesicle practically fills the host cell. The end of the cycle is reached by 30 hours, with the appearance of two kinds of mature particles, the one a small spherical body about 200 m μ in diameter and containing a central body of electron-dense material, and the other a larger ovoid particle, 300 × 500 m μ , which is reticulate or granular in structure. The analogy to the successive stages of bacterial cytomorphosis during growth is striking, but, since the microorganisms of this group are set somewhat apart from viruses, it does not follow that virus growth cycles in general might be expected to be reflected in such a succession of morphological types.

In summary, there is as yet no convincing evidence of the occurrence of bacterial life cycles other than the cytomorphosis occurring during the population growth cycle. The virus-like agents of the psittacosis-lymphogranuloma group show a similar pattern of successive morphological types of particle, but the clearly apparent stages in the developmental cycle of viruses are characterized by immunological methods and infectivity.

PHYSIOLOGICAL VARIATION

Variations in the so-called physiological characteristics of a microorganism are not fundamentally different from morphological variations, in that the latter involve the synthesis of cell structures, but in practice they

are taken to be those which do not necessarily have a morphological expression. These include the ability of a microorganism to decompose sugars and other substrates with the appearance of characteristic end products (the biochemical properties of microorganisms), their nutritive requirements, susceptibility to infection with bacterial viruses, immunological character, and, in the case of pathogenic forms, virulence.

All of these may be equated on the common basis of the synthetic abilities of the microorganism. The decomposition of various substrates is obviously dependent upon the elaboration of the appropriate enzymes, and nutritive requirements are an expression of synthetic abilities in that a substance required for growth (in the sense that it must be supplied preformed) is one that the microorganism cannot synthesize. Susceptibility to infection with bacterial viruses is dependent, in part at least, on the presence of appropriate receptors in the cell wall structure, a product of synthesis. Similarly, immunological character is an expression of the antigenic specificity of components of the cell substance of the microorganism. or the products of its metabolism, both the result of synthesis. The nature of the virulence of pathogenic microorganisms is not fully understood, but it is indicated that the ability to produce disease is in large part a consequence of the production of toxic substances, ranging from potent exotoxins to enzymatic or kinase-like activities that facilitate invasion of the tissues of the host (Chap. Nine). Such substances are also products of microbial synthesis.

The identity of a microorganism in all these respects is thus referable to the operation of directed control mechanisms within whatever limitations are imposed by the environment. It follows that microbial variation arises from alterations in genetic control mechanisms and/or their functioning within the microcosm of the environment to give phenotypic expression of genotypic character.

ENVIRONMENTAL SELECTION

The demonstration of microbial variants almost always requires the utilization of a selective environment such as a culture medium that may be differential as well as selective or an experimental animal or its

equivalent in the case of virulence studies. This is because ordinarily only a minute portion of the microbial population differs from the parent strain, and its emergence from the population to recognizable proportions is usually dependent upon an environment which is more favorable to the development of the variant than of the parent strain.

This approach is applicable directly in the case of variants in which the change is positive, in the sense of the acquisition of the ability to ferment a sugar, to produce infection in an experimental animal or the development of resistance to an antimicrobial substance. For example, when a substrate which the parent strain is unable to utilize is present in a culture medium, the variant which is able to decompose it may be able to outgrow the parent strain. If the substance is a sugar it may be incorporated in an agar medium together with an indicator. such as an acid-base indicator or Schiff's reagent, so that the colonies of the variant will be colored while those of the parent strain are not. Or, when the parent strain requires, for example, an amino acid for growth, variants which are able to synthesize the amino acid grow in a medium lacking it while the parent strain does not. In the same way, a culture medium may include an antimicrobial substance, such as an antibiotic, which prevents the growth of the parent strain but not that of a resistant variant, or after inoculation with bacteria the medium may be inoculated with bacterial virus which inhibits a susceptible parent strain but not a resistant variant. Similarly, virulent pathogenic microorganism grows readily in the tissues of the host, while the avirulent form fails to establish an infection and is destroyed by host defense mechanisms.

Variations involving losses require a different approach in that the growth of the parent is not suppressed in the absence of the substrate while that of the variant is. Consider a parent strain which does not require tryptophan and a variant which does; both will grow on a medium containing the amino acid, but only the parent strain on a medium lacking it. Individual colonies may be subcultured from the complete medium and tested, but this procedure is laborious and, for the isolation of such variants on any scale, an indirect method is required.

In this connection advantage may be taken of the fact that penicillin affects actively multiplying bacteria to a much greater extent than those which are not multiplying. An agar medium deficient in some nutrient, such as an amino acid, is inoculated and incubated for sufficient time to allow active multiplication of those cells which do not require the amino acid. It is then treated with penicillin to selectively destroy the actively multiplying cells, the activity of the penicillin is neutralized, and the inoculated medium is overlaid with agar medium containing the amino acid, or other substance, not present in the first medium. The cells which were unable to multiply in the absence of the substance in the first instance, and so were not affected by the penicillin treatment, grow out in the second medium.

ADAPTATION103

For present purposes the term adaptation may be interpreted broadly as covering all microbial variations which are consistent with an increased physiological compliance with the demands of the selective environment. The adaptive response is of two kinds. One of these is actually a response to the environment in that it is induced, more or less directly, by an environmental factor. The other is not a response in the literal sense, and its adaptive character is a consequence of the appearance of a random mutant which, purely by chance, has greater survival value than the parent from which it was derived. In a general way, the induced variation usually develops slowly and the adaptation seems to be continuous, while spontaneous mutants appear abruptly and the adaptation which is dependent upon a series of mutations occurs as discrete steps. It is often not possible to distinguish between these two kinds of adaptation, and both may be involved in what seems to be a single adaptive process.

ATTENUATION

The term attenuation is ordinarily loosely used to mean altered virulence of a pathogenic microorganism. It may indicate a simple loss of ability to produce disease in a general sense or a reduction in virulence for one host species accompanied by an increase in virulence for another host species.

Loss of virulence. In general, most pathogenic bacteria tend to lose virulence when kept in culture on artificial mediums. For example, pneumococci rapidly lose virulence. for the mouse and in even a very few transfers on enriched mediums the minimal lethal dose increases by several hundred-fold. Staphylococci, however, retain their virulence over many transplants on artificial mediums but eventually become relatively avirulent. A few bacteria, such as the anthrax bacillus, seem to retain virulence almost indefinitely, but this is not common. Such losses in virulence are general in character in that the bacteria become less virulent for a variety of experimental animals and presumably arise as a consequence of adaptation to an environment other than that of the animal body.

The artificial environment may be deliberately made somewhat toxic in order to bring about such changes. Simple aging in the case of Pasteur's cultures of the fowl cholera organism was sufficient to reduce virulence so that a fatal infection was not produced, and the attenuated strain of bovine tubercle bacillus known as BCG was carried on a bile-containing medium until its virulence was apparently completely lost.

Loss of virulence may be accompanied by changes in other characteristics such as marked diminution in capsule formation by the pneumococcus, a loss of golden pigment by Staphylococcus aureus and somewhat less fastidious nutritive requirements. In many instances the change is dissociative in nature, and loss in virulence is associated with a shift from the smooth form. In most bacteria, of course, virulence is markedly reduced by the S-R dissociation, and a change of this kind may occur in vivo, presumably under the influence of antibody; for example, the typhoid bacilli excreted by chronic carriers are often rough, avirulent forms.

Animal passage. Virulence may often be restored by animal passage, e.g., successive and repeated infection and re-isolation of the bacterium through a series of experimental animals. It cannot be concluded that the microorganisms are individually altered in the restoration of virulence by animal passage, and it is more probable that the animal acts as a highly selective screen, separating out those few bacteria in the inoculum which multiply most rapidly in the tis-

sues. The restoration of virulence is usually accompanied by a restoration of other characters associated with it such as capsule formation.

Modification of virulence. The virulence of a microorganism may be modified by passage through another host species, and sometimes, though not invariably, virulence for the original host species is reduced. The classic example of attenuation by animal passage is that of Pasteur's attenuation of the rabies virus by adaptation to the rabbit brain. The original strain from dogs, "street virus," kills rabbits in about two weeks following subdural inoculation, after some 20 passages it kills in eight days, and after an additional 20 or more passages the period may be reduced to seven days but cannot be reduced further. This "fixed virus" will not produce rabies on subcutaneous inoculation and so may be used as an immunizing agent. Such attenuation or adaptation to a new host is very common among the viruses and includes the adaptation of a variety of viruses to the chick embryo, the adaptation of vellow fever virus to the mouse brain, etc. For example, on primary isolation in the embryonated hen's egg, influenza virus forms relatively little hemagglutinin for the chicken erythrocyte, but after a few passages hemagglutinin is formed in abundance. This has been designated the O-D variation of influenza virus and represents an adaptation to the new host tissue. This virus can be further modified to, for instance, the mouse lung, or its naturally occurring pneumotropism altered by successive passage in the mouse brain so that, like the adapted yellow fever virus, it becomes neurotropic.

BIOCHEMICAL VARIATION

Variation in the biochemical properties of bacteria, such as fermentation of sugars, decomposition of proteins and amino acids, nutritional requirements, resistance to antibacterial agents, and the like, occurs with some frequency. Some of these develop more or less gradually on continued cultivation in selective mediums and resemble the process of attenuation of virulence.

Adaptation and training. Such variation in nutritive requirements is the basis for the general observation that the more fastidious pathogenic bacteria are frequently more difficult to cultivate on primary isolation and

enriched mediums are required, while, after being carried in culture for some time, they grow more rapidly and profusely and on somewhat simpler mediums. For example, on primary isolation Brucella abortus requires an increased carbon dioxide tension, but after a few subcultures this may be dispensed with. Similarly, the gonococcus and meningococcus require, on primary isolation, both an increased carbon dioxide tension and an enriched medium, usually a heated blood medium. After a few subcultures, however, it is no longer necessary to supply carbon dioxide, and eventually growth occurs in simpler mediums. The adaptive process may be initiated, or markedly accelerated, by culture of bacteria in mediums designed to select variants. Pathogenic staphylococci become less fastidious in their nutritive requirements when maintained in the laboratory as noted above, and variation in this direction may be accelerated by forcing the bacteria to grow in a medium that is made successively less and less complex. For example, the amount of a required amino acid present in a synthetic medium may be gradually reduced over successive transplants, until finally the microorganism no longer requires it. By such means fastidious staphylococci have been trained or adapted to grow in a simple medium containing only glucose and an ammonium salt. Similarly, typhoid bacillus strains requiring the single amino acid tryptophan may be trained to grow in its absence, and strains of dysentery bacilli capable of growing in a glucose-ammonium salt medium, supplemented only with nicotinic acid, may be adapted to dispense with the vitamin.

Ability to ferment carbohydrates may also be either acquired or markedly enhanced by continued cultivation in the presence of the substrate or by very heavy inoculation of highly specific mediums in which the substrate is the only nutritive material. Still other adaptations such as to changes in pH, increased incubation temperature, and the like, also occur but are usually not marked.

Discontinuous variations. Some microbial variants appear much more rapidly than those developing in the kind of adaptations described above, often occurring in the first culture on a selective medium. They are regarded as expressions of a sudden, discontinuous change, or mutation in the genic

sense, in the genetic apparatus of the microorganism.

Lactose fermentation. The classic example of this kind of variation is that shown by certain strains of coliform bacilli which are atypical in that they are unable to ferment lactose, but which throw off lactose-fermenting variants. This phenomenon was observed as early as 1907 by Massini, and the strains of coliform bacilli were named Bacterium coli mutabile.

The phenomenon is demonstrated by culture of the bacteria on an agar medium containing lactose together with an acid-base indicator which turns red in the presence of acid. The primary growth consists of white colonies of the nonlactose-fermenting parent strain, and on continued incubation a secondary growth of the lactose-fermenting variant appears in the form of red papillae on the white colonies. On subculture on the same medium, the lactose-fermenting variant breeds true, while the parent strain again produces white colonies on which red papillae appear. The enzyme produced by the variant, but not by the parent strain, is the adaptive enzyme β -galactosidase. As an adaptive enzyme (see below), it is produced only in the presence of an inducer, in this case lactose and certain related compounds, and the variant is characterized by the ability to form the enzyme and its potentiality is realized in the presence of the substrate. In genetic terminology, therefore, the genotype of the parent strain is lac- and that of the variant lac+, but both are phenotypically the same in the absence of inducer.

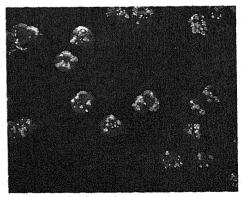

Figure 55. Colonies of E. coli mutabile on lactose agar. Note the lactose-fermenting papillae of the variant appearing on the nonlactose-fermenting colonies. (Parr.)

Other variations. Many other variants of this rapidly appearing kind are well known and have been studied extensively, especially variants resistant to chemotherapeutic agents (see below) and those requring essential metabolites such as amino acids and purines. These distinctive characters have been used as markers in studies of the genetics of microorganisms for they behave in a manner consistent with the assumption that they are determined by genes or their equivalent.

Analogous variations occur among the viruses also. The characteristics subject to variation are not physiological, since these agents apparently have no independent metabolism, but are characteristics such as plaque size and appearance and burst size of the bacterial viruses, and immunological changes, virulence, and cytotropism of animal viruses, of which influenza is the best known in this respect.

Variation of this kind cannot be dissociated from the adaptive processes described above. Such a variant, with some small advantage in growth rate over the parent strain in a selective environment, would displace the parent type more or less slowly to give the appearance of a slowly developing adaptive response. The microbial population tends to obscure the nature of the processes of variation, but it is likely that spontaneous mutation plays a significant part in adaptation.

RESISTANCE TO CHEMOTHERAPEUTIC AGENTS^{35, 82, 91}

The development of strains of microorganisms resistant to chemotherapeutic agents was observed as early as 1907 in connection with the parafuchsin therapy of trypanosome infections in mice. It has been observed since that microorganisms will become resistant to a variety of compounds, including aniline dyes (parafuchsin, acriflavine), aromatic arsenicals (Atoxyl, arsacetin, tryparsamide), aromatic compounds of antimony (stibenyl, Fuadin), suramin (Bayer 205), styryl quinoline derivatives, guanidine compounds, sulfonamides, and antibiotics.

Prior to the introduction of sulfonamides, therapy of infectious diseases was limited to the diseases caused by spirochetes and animal parasites. When sulfonamides, and within a few years antibiotics, became available, they became so widely used that the problems created by microbial resistance to chemotherapeutic agents assumed large proportions.

The facility with which resistant strains of microorganisms develop is a property of both the microorganism and the antimicrobial substance. For example, staphylococci become resistant to many kinds of antibiotics very readily, the gonococcus becomes resistant to sulfonamides but apparently less readily to antibiotics, while pneumococci and streptococci are only occasionally resistant to sulfonamides or antibiotics but not to a practically important degree. Conversely, it is characteristic of streptomycin that almost all kinds of bacteria become resistant to it, often very rapidly. Microbial resistance may be considered here from two points of view, that of natural occurrence and therefore inferentially in vivo, and that of experimental production in the laboratory or in vitro.

Resistance acquired in vivo. The development of resistance under natural conditions of use of antimicrobial substances for therapeutic purposes is expressed as an increased proportion of resistant strains among those found in disease conditions or in carriers. When the sulfonamides were first introduced into general use, they were effective in the treatment of the majority of cases of gonorrhea, but within a relatively short time, three or four years, only a minority of cases of this disease could be treated effectively with these compounds, and strains of gonococcus isolated from refractory cases were shown to be resistant. Subsequently the response to repository penicillin has become less satisfactory, and is considered to be a factor in the increased prevalence of gonorrhea.¹⁸ With the consequent decline in the therapeutic use of sulfonamides, there is now evidence that the prevalent strains are becoming more sensitive to sulfonamides, and these compounds may again be effective.113

Similarly, the proportion of staphylococcus strains resistant, first to penicillin, subsequently to tetracyclines and other antibiotics, and often showing multiple resistance, increased at a rapid rate as the antibiotics became generally available and widely used.⁸ There is evidence too that there is an appreciable sulfonamide resistance developing among the dysentery bacilli.¹⁰⁹

The occurrence of resistance is related to the frequency with which antibiotics are used. Staphylococcal resistance has been studied most intensively, is of the most practical importance, and may be used here as an example. Resistance to penicillin, the first generally used antibiotic, appeared first, and then resistance to tetracyclines and chlormaphenicol, and subsequently to newer antibiotics such as erythromycin. Chloramphenicol contains a nitro group (Chap. Six), and after a number of cases of aplastic anemia were associated with its continued administration, it was used much less commonly. Coincident with this, there was a decline in the proportion of staphylococcus strains resistant to it. This, and other evidence, such as that of reversal of sulfonamide resistance among gonococci, suggests that, as measured by the proportion of resistant strains, bacterial resistance in nature is not established permanently, but rather is maintained by continued general use of a chemotherapeutic agent. The tendency to reversion to sensitivity, coupled with the variety of chemotherapeutic agents now available, opens the way to circumventing the problems of effective chemotherapy. In Hammersmith Hospital in London, for example, it has been possible to reverse the tendency to increasing antibiotic resistance of staphylococci and reduce the frequency of staphylococcal infection by balancing the kind of chemotherapeutic agents used against the observed frequency of resistance, together with special attention to sterilization and prevention of cross-infection.9

While, as might be anticipated, resistant strains occur in greatest proportion in hospital populations, for the most part such resistant strains are not introduced by the patient, but rather infection of the patient with resistant strains is acquired from hospital personnel. The source of infection is most often carriers, usually nasal carriers, and the incidence of nasal carriers of resistant staphylococci among surgeons and surgical personnel may become high. It is not uncommon to find that a wound infection following surgery is one with staphylococci having multiple resistance which does not respond to treatment with the commonly used, and generally available, antibiotics. The problem so created has reached such proportions that bacteriological control of surgical personnel has become necessary in some instances. Such studies as have been made of the incidence of resistant staphylococci in the general population suggest a proportion of perhaps 20 per cent, though this may vary widely and be much lower. In contrast, the proportion of penicillin-resistant staphylococci in hospital personnel commonly ranges from 60 to 85 per cent in this country and in Western Europe. The general problem of the incidence and behavior of bacterial strains resistant to chemotherapeutic agents has been studied intensively.^{32, 52}

Origin of resistant strains. It is not completely clear whether resistant strains of microorganisms are pre-existing and make up a small, possibly minute, portion of all strains, or whether they arise for the most part in the individual undergoing chemotherapy. In the first instance, when the microorganism is primarily a parasite of man, the widespread use of a chemotherapeutic agent alters its environment to favor the survival of resistant strains. Under such circumstances it is to be expected that the proportion of resistant strains would increase.

It is well established, on the other hand, that resistant strains of microorganisms appear in persons originally infected with sensitive strains who are undergoing chemotherapy, especially prolonged therapy. This is most commonly observed in tuberculosis in which the prolonged therapy required, combined with the marked tendency of the microorganism to develop resistance to the kinds of chemotherapeutic agents used - streptomycin, p-aminosalicylic acid (PAS), and isoniazid—facilitates the emergence of resistant strains of the tubercle bacillus. When such infections are treated with a combination of two chemotherapeutic agents, the occurrence of resistant strains is markedly reduced. Many detailed studies have been made, and in a representative investigation85 it was found that when patients were treated with isoniazid alone, 6 per cent yielded isoniazid-resistant strains of tubercle bacilli at the end of one month, and 58 per cent at the end of six months. When the disease was treated with combined antimicrobial substances, streptomycin in combination with PAS or with isoniazid, at the end of three months only 2 per cent of patients yielded streptomycinresistant strains in the first instance and isoniazid-resistant strains in the second. Still other patients treated with PAS only, prior to the institution of combined therapy with streptomycin and PAS, showed streptomycin-resistant strains in 70 per cent at the end of three months of combined therapy when their tubercle bacilli had been initially resistant to PAS, but this was found in only 9 per cent of those whose bacilli were initially sensitive to PAS.

The suppressive effect of combined therapy on the emergence of resistant strains supports the assumption that the resistant strain is made up of the progeny of a resistant mutant, and the growth of a mutant resistant to one of two chemotherapeutic agents used in combination is suppressed by the other. Assuming that the appearance of such mutants is a random, and therefore independent, event, the probability of occurrence of a double mutation is given by the product of the probabilities of each and becomes extremely small.

resistance.27, 110 Un-Infectious drugfortunately the mechanisms of acquiring drug resistance are not always this simple. at least among the gram-negative enteric bacilli. It was found by Japanese workers in 1960 that multiple resistance of dysentery bacilli, involving streptomycin, chloramphenicol, tetracycline, and sulfonamides, is transferred en masse, not only to other shigellas but also to other enteric bacilli, in mixed culture and independent of the sex factor (see below). The transfer of such multiple resistance is a function of an episome⁹⁰ designated the R(resistance)-factor which is independent of the cell chromosome and, in the automonous (i.e., cytoplasmic) state replicates more rapidly than the chromosome. It has been found³ that the transfer of multiple resistance is dependent upon two factors, the R-factor and a separate transfer factor; the latter is functional in the transfer of episomal factors in addition to the R-factor. The earlier designation of the R-factor as the RTF, or resistancetransfer factor, is thus inappropriate. The interrelationship is demonstrable in, for example, an experiment in which three strains of bacteria-one containing the Rfactor alone, another only the transfer factor, and the third neither-are grown in mixed culture. Resistance is transferred to the strain containing only the transfer factor. and as well to that containing neither, but the R-factor would not be transferred in the absence of the transfer factor. Transfer of multiple drug resistance also occurs in vivo in the intestinal tract.⁵³

The possible, or even probable, development of resistant strains of enteric pathogens, such as Salmonella, in domestic animals through the use of feeds containing antibiotics for growth-promoting purposes has been a matter of considerable concern.⁷¹

Induced resistance. Almost as soon as the antibacterial chemotherapeutic agents became available it was found that strains of microorganisms resistant to them could be readily produced in the laboratory. Induced resistance cannot be considered to differ fundamentally from the processes of development of resistant strains isolated in increasing proportions with the general use of antimicrobial drugs. The infected individual undergoing treatment constitutes a selective environment conducive to the survival of resistant mutants, while in induced resistance the selective environment is that provided by the antibiotic-containing culture medium.

The usual procedure is to grow the bacteria in vitro or in vivo in the presence of increasing concentrations of the antimicrobial substance. This may be carried out by serial culture, or by culture on the gradient plate. The latter is prepared by allowing an agar medium containing the antibacterial substance to solidify at an angle in a petri dish and overlaying it with medium lacking the substance. The activity diffuses from the lower to the upper layer, giving a gradient in concentration on the surface of the medium from one side to the other. Bacterial cultures are streaked across it in the direction of the gradient, and, after incubation, the growth at the limiting concentration may be streaked into the higher concentration area, etc. Or, with some antibiotics, a series of agar mediums containing varying concentrations of the activity may be inoculated heavily, and the colonies growing out at various concentrations are resistant. Resistant variants may be produced in vivo by animal passage in the case of pathogenic microorganism in experimental animals treated with subcurative amounts of chemotherapeutic agents.

Resistance may appear relatively rapidly, even in the first subculture, or more slowly over successive transplants. The maximum attainable may be of a low order, a few hundred-fold or less in the maximum non-inhibitory concentration of the activity, or many thousand-fold. The degree of resistance and the rate of its emergence are, as indicated earlier, to a considerable extent characteristic of the microorganism and of the antimicrobial agent. The resistance so produced persists, to a greater or lesser extent, through successive subcultures in the absence of the chemotherapeutic substance.

For example, the development of penicillin resistance usually requires a considerable period of adaptation of the parent strain to increasing concentrations of the antibiotic. A resistance to several thousand-fold the initial inhibitory concentration may be attained with staphylococci, but only of a much lower order, ten-fold to a hundred-fold with streptococci and pneumococci. In contrast, streptomycin resistance appears very rapidly, often on first subculture, in many kinds of bacteria and is of a very high order. In general, the higher the level of resistance produced, the longer it persists in culture in the absence of the antimicrobial substance. Thus penicillin-resistant streptococci revert relatively rapidly to the original sensitive state, but high resistance to streptomycin appears to be practically permanent.

With the development of antiviral substances it has become evident that viruses also may become drug-resistant, or drugdependent (see below).84 The inhibition of picornaviruses in cell culture by guanidine. or by $2-(\alpha-hydroxybenzyl)$ -benzimidazole has been described elsewhere (Chap. Six). These substances are virustatic and viral replication in cell culture does not occur in their presence, but if contact is maintained the virus becomes resistant and/or dependent and grows in the presence of the inhibitor. 107 Thus poliovirus may be rendered guanidine-resistant, and the dependent strains are no longer virulent for the monkey.65 Among the DNA viruses, it has been found that herpesvirus may be made resistant to 5-iodo-2'-deoxyuridine, and infectious bovine rhinotracheitis virus may become resistant and dependent upon the fluoro and bromo deoxyuridines. 100

Dependent strains. The occurrence of variants not only resistant to certain of the antimicrobial substances, but actually requiring them for growth, was observed first

with sulfonamide and Neurospora and streptomycin and meningococcus, and subsequently has been found to occur with some frequency. Such variants are known as dependent strains.

The significance of this kind of variant lies in the fact that it suggests that some antibiotic substances function as specific metabolic inhibitors. There are two more obvious explanations of this phenomenon. One, the metabolic reactions of the microorganism have become so altered that the analogue has displaced the original metabolite in a metabolic sequence, and is now required. An alternative possibility is that dependent microorganism produces antagonist (see below) in such large amounts that it is toxic, and the antimicrobial substance must be present to neutralize this toxicity and allow growth. The sulfonamidep-aminobenzoic acid relation has been discussed elsewhere, and in this connection it is of particular interest that p-aminobenzoic acid acts as an antimetabolite on sulfonamide-dependent variants. A similar phenomenon has been described for the antimetabolite pyrithiamin. It is not known whether certain of the antibiotics, such as streptomycin, function as antimetabolites, but the occurrence of dependent variants suggests that this may be true.

When pathogenic microorganisms are made drug-dependent, they are unable to infect a susceptible animal host unless the animal is concurrently treated with the chemotherapeutic agent. Such drug-dependent strains have been of considerable interest as possible immunizing agents against infectious diseases, such as brucellosis, to which conventional heat-killed vaccines do not produce an effective immunity.

Cross-resistance. A strain of bacteria may be resistant to more than one kind of antimicrobial substance. When the history of the strain is known, as in the case of variants produced in the laboratory, it is clear that this resistance is of two kinds. One is multiple resistance in which a microorganism has been made resistant, one by one, to a number of antimicrobial substances. This is often encountered in bacterial strains, notably staphylococci isolated in resistant form. The other is cross-resistance in which a variant made resistant to one agent is found to have acquired resistance to another. This is almost uniformly true among

the tetracyclines. Cross-resistance occurs only rarely between unrelated compounds and is of a low order. In relatively rare instances increased resistance to one agent may be associated with increased sensitivity to another.

Physiology of resistance.⁷² Since the antimicrobial substances having therapeutic utility act by inhibition of growth processes, the basis of resistance to such substances is probably to be found in alteration of the metabolic processes of the microbial cell. The resistant variant may be presumed to differ in this respect from the parent strain, and the more obvious possibilities of the way in which this may occur are:

Synthesis of antagonists. The resistant variant may neutralize the activity of the chemotherapeutic agent by production of antagonists in greater than normal amount. This is clear-cut in the case of some sulfonamide-resistant variants. For example, many of the sulfonamide-resistant gonococcus and staphylococcus variants are resistant because they produce excessive amounts of inhibitor, often but not necessarily p-aminobenzoic acid. Similarly, diphtheria bacilli made resistant to the inhibitory effect of the analogue pantolyl taurine synthesize pantothenic acid sufficient to support growth in the presence of the inhibitor.

It is doubtful how far this approach may be generalized. For example, all sulfon-amide-resistant gonococci and staphylococci do not form increased amounts of sulfon-amide antagonist, and some other mechanism is operative. In addition as yet specific antagonists of many antimicrobial substances, especially the antibiotics, are not known.

Decomposition of the inhibitor. Resistance to penicillin has been found to be associated in many, but not all, instances with the production by the resistant bacterial strain of an enzyme, or enzymes, which decompose the antibiotic. The best known of these, and the one apparently responsible for in vivo resistance, is penicillinase, or penicillin β -lactamase, which splits the penicillin molecule containing the lactam linkage to give inactive penicillinoic acid. It is an adaptive, i.e., inducible, enzyme which occurs extracellularly in gram-positive bacteria and is formed by a number of kinds of bacteria, notably staphy-

lococci and Bacillus species. Penicillinase production probably accounts for resistance in almost all strains of penicillin-resistant staphylococci isolated from infections, and it has been shown³⁰ that its induction occurs in vivo as well as in vitro. The penicillinases produced by gram-negative bacteria tend to be set apart, in that they are intracellular and noninducible and are produced in relatively small amount.95 It has been suggested that, since the high lipid content of the cell wall of the gram-negative bacteria makes them relatively impermeable to penicillin, small amounts of intracellular penicillinase suffice to inactivate penicillin in resistant organisms. Some penicillins differ sufficiently in structure, e.g., dimethoxyphenyl penicillin (methicillin) and 3-phenyl-5methyl-4-isoxazolyl penicillin, that they are not decomposed by the β -lactamase, and are valuable in the treatment of infecwith penicillin-resistant bacteria. staphylococci in particular.

Penicillins are inactivated by other enzymes of bacterial origin. Penicillin acylase (penicillin amidase)⁴⁰ splits the peptide linkage by which the side chain is attached to the nucleus of 6-amino penicellanic acid, and the remaining nucleus is relatively inactive. This enzyme apparently plays little or no part in penicillin resistance *in vivo* in part because of its high pH optimum, but it has been extremely valuable in the preparation of "semisynthetic" penicillins (Chap. Six). It is produced by both gram-positive and gram-negative bacteria.²⁵

In some instances, especially in penicillin-resistant staphylococci, decomposition of the antimicrobial agent seems not to be a common mechanism of resistance. It has been reported, 5 however, that multiple resistance of R-factor-containing enteric bacilli is associated with the formation of enzymes that decompose the antibiotics. Intracellular, noninducible enzymes which degrate chloramphenicol, dihydrostreptomycin, and kanamycin have been found in resistant strains containing the R-factor, but not in strains made resistant by adaptation.

Alternative metabolic pathways. A third way in which the variant may become resistant to an antimicrobial substance is by the development of an alternative equivalent metabolic pathway to replace that affected by the agent. The precise nature of the in-

hibiting effect is not known in most cases, but if such an alteration occurs, it might be expected to be accompanied by demonstrable physiological differences between the sensitive microorganism and its resistant variant. There is a great deal of evidence that resistance is accompanied by a variety of changes in metabolic processes such as altered nutritive requirements and impaired carbon metabolism.

For example, the assimilation of glutamic acid by staphylococcus described elsewhere (Chap. Three) in connection with the osmotic barrier, does not occur in penicillinresistant variants, and free glutamic acid is not found in the cell, indicating that the variant has dispensed with the assimilatory mechanism and synthesizes its own glutamic acid. Consistent with this is the general observation that penicillin-resistant staphylococci which do not produce penicillinase no longer require as many preformed amino acids and bacterial vitamins. 15 Among the enteric bacilli, the converse has been observed, i.e., variants showing more complex nutritive requirements may be less sensitive to the antibacterial activity of penicillin than the parent strain.79

More specific changes have been found by a number of workers, especially Sevag and his co-workers.87,93 It has been shown, for instance, that pneumococci resistant to various chemotherapeutic substances have altered flavoprotein enzyme activity, possibly arising from a modification of the protein moiety, and reduced dehydrogenase activity and ability to oxidize glucose and intermediates such as lactate and glycerol. Similarly, streptomycin-resistant coliform bacteria partially or completely lose the ability to metabolize pyruvate anaerobically, and some variants partially replace the normal anaerobic phosphoroclastic metabolism of pyruvate, which is sensitive to streptomycin, with a streptomycin-resistant dismutative process. Pyruvate metabolism is altered also in chloramphenicol-resistant staphylococci so that it is not utilized but acts as a hydrogen acceptor to accumulate additional lactic acid in the medium.⁷⁷ Isoniazid resistance of tubercle bacilli is accompanied by a loss of the ability to produce catalase and a decreased virulence for the guinea pig, and the former may well be related to the observation that hemin antagonizes the antibacterial effect of isoniazid on tubercle bacilli.⁵⁸ Similarly, indophenol oxidase-containing extracts of colon bacilli resistant to chlortetracycline have been found not to be inhibited by the antibiotic, while such extracts of sensitive bacilli are inhibited.⁸⁹

While data such as these make it clear that the physiological processes of many bacteria are appreciably, or even profoundly, altered in resistant variants, available information is as yet too fragmentary to make it possible to discern a pattern in the physiological changes accompanying resistance.

It is not necessary to assume that a single mechanism is operative in the development of resistance to chemotherapeutic agents in that the foregoing are not necessarily mutually exclusive. In fact, the utilization of more than one mechanism in an apparently single adaptation is indicated in the observation that, in the adaptation of coliform bacilli to sulfanilamide there is first a reduction in the prolonged lag period interpreted as the development of an alternative metabolic sequence, followed by an enhanced growth rate attributable to the formation of an antagonist.

ADAPTIVE ENZYMES^{23, 80, 81, 97, 99}

The ability of a microorganism to decompose a substrate may be very rapidly enhanced in the presence of that substrate. Although known for many years, this particular kind of bacterial variation has been the subject of renewed interest as enzyme adaptation. The enzymes which may be formed under the influence of the presence of substrate have been called adaptive enzymes in contrast with those which are formed whether or not the substrate is present, the constitutive enzymes. The formation of adaptive enzymes may be demonstrated by cultivation of the bacteria in a medium containing the substrate and then testing the organisms for enzymatic activity, or a washed suspension of bacteria grown in the absence of the substrate may be mixed and incubated with it. In the first instance, activity is immediately apparent, the bacteria having formed the adaptive enzyme during growth, and in the second a latent period varying from 30 minutes to two to

four hours occurs before rapid decomposition of the substrate begins.

A number of bacterial enzymes are adaptive in that they are formed wholly or in large part in the presence of the substrate. Among these, the β -galactosidase of the colon bacilli and penicillinase formation by B. cereus have been widely used as model systems. The amino acid decarboxylases are formed for the most part in the presence of the substrates. Many of the bacterial proteases are adaptive enzymes, for only small amounts of the enzymes are formed in the absence of protein, but filtrates from cultures in protein-containing mediums are actively proteolytic. Various other bacterial enzymes are adaptive also; thus, the enzyme tetrathionase, responsible for the reduction of tetrathionate to thiosulfate by Salmonella, and nitratase, which catalyzes the reduction of nitrate to nitrite by the colon bacillus, are adaptive as is the enzyme penicillinase formed by Bacillus species. The distinction between adaptive and constitutive enzymes may not always be a sharp one, for frequently, if not invariably, as in the case of the bacterial proteases. the adaptive enzyme is not completely lacking in the absence of the substrate.

The property of inducing adaptive enzyme formation is not necessarily confined to the substrate. Thus in the β -galactosidase adaptation of the colon bacilli, melibiose and galactose are inducers but not substrates, neolactose is a substrate but not an inducer, and thiophenyl-β-galactoside is a competitive inhibitor of the enzyme activity but is not an inducer. Lactose is, of course, both substrate and inducer in this instance. The adaptation, as assayed by the ability to ferment lactose, is more complex than this, for it is now clear that the ability to ferment involves not only the β -galactosidase, but the cell must also be permeable to lactose. This last is a function of the enzymatic activity designated permease^{20, 22} which is also an adaptive enzyme (Chap. Three).

The question of whether or not the formation of an adaptive enzyme is associated with bacterial multiplication is one of considerable interest. In general it appears that some degree of multiplication is essential (cell division occurs even in suspensions of washed bacteria), and it has been shown in the formation of β -galacto-

sidase by colon bacilli that the amount of enzyme was proportional to the number of new cells. In the majority of instances actual proliferation of the cells need not occur, though synthesis of the enzyme takes place during the latent period. The adaptive formation of formic hydrogenlyase by nonproliferating coliform bacilli requires a source of both energy and amino acids and is inhibited by assimilatory poisons such as nitrate and nitrite60 and by x-irradiation of the cells. In general, adaptive enzymes are formed under conditions of nitrogen starvation when there is no net increase in the number of cells, and this is probably a consequence of protein turnover in the nonproliferating cells.

It is both relevant and significant to note that substantially all, rather than a select few, of the cells subjected to the inducersubstrate participate in the formation of the enzyme. This, and the requirement for amino acids, indicates total synthesis of the enzyme. The observed lag in the appearance of enzymatic activity is presumably due to activation of the enzyme, for total synthesis is very rapid; penicillinase, for example, is formed within 30 seconds. Adaptive enzyme formation is inhibited by growthinhibiting antimicrobial substances this is taken to suggest that these substances inhibit synthesis of constituent protein by the bacterial cell. It is of interest in this connection that kinetic considerations have shown that at least in the adaptive formation of penicillinase by Bacillus cereus, the inducer-substrate, penicillin, cannot be incorporated into the enzyme but must function catalytically, in that each mol of penicillin fixed or destroyed gives at least 10 mols of the enzyme.80

The phenomenon of enzyme adaptation has been made use of, especially by Stanier, in the elucidation of adaptively controlled metabolic pathways. In a chain reaction controlled by adaptive enzymes represented

$$A \xrightarrow{\sim} B \xrightarrow{\sim} C \xrightarrow{\sim} D \xrightarrow{\sim} etc.$$
 $E_a \xrightarrow{} E_b \xrightarrow{} E_c \xrightarrow{} E_d$

the reaction A B is catalyzed by the adaptive enzyme E_a, B-C by enzyme E_b, etc. When any intermediate is supplied, the chain reaction continues to completion since the product of one reaction is the substrate for the next, and in its presence the appropriate adaptive enzyme is formed. Thus substances presumed to be intermediates can be tested for actual participation in the chain reaction; *i.e.*, if the compound is dissimilated immediately by cells adapted to substrate A, for example, but not by cells not adapted to A, it is highly probable that it is an intermediate. This technique has been applied, in whole or in part, to analysis of adaptive patterns in the oxidation of Krebs cycle components, aromatic compounds including tryptophan, tyrosine, and purines.

CONJUGATION AND RECOMBINATION^{2, 39, 61}

The possible occurrence of sexuality among bacteria and related microorganisms has permeated the interpretations of variation phenomena for many years, but it was not until 1947 that unequivocal evidence for the recombination of marker characteristics, and inferentially conjugation, between unlike cells was presented by Lederberg. In essence this consisted of the isolation of radiation-induced variants of the parent K-12 strain of coliform bacilli, characterized by physiological differences such as requirements for specific amino acids. When such variants are grown in mixed culture, progeny may be isolated in which the markers occur in the possible combinations, including combinations not present in the original strains, and in kind and proportion to be expected on the assumption of a conjugative recombination.

Bacterial sexuality.⁵¹ It would appear to be implicit in the occurrence of recombination that the cells which conjugate differ from one another, *i.e.*, that conjugation has a sexual basis. It is now clear that there is a sex factor, F, present in some cells and not in others. These are designated F+ and F-, the F+ cells being donors, or males, and the F- cells the recipients, or females. In the F+ cell the F factor, like the R factor described above, is autonomous and replicates independently of the bacterial chromosome, though at about the same rate, and there is one, or possibly as many as three, per F+ cell.

When F+ cells are mixed with an excess of F- cells, recombination is a relatively rare event; about one recombination occurs per 10,000 F+ cells. The observed recom-

36

bination is due to the presence of a mutant of F+ cells, designated Hfr (high frequency recombination), in which the F factor is integrated in the bacterial chromosome. Thus when conjugation occurs between an Hfr cell and an F- cell, all or part of the bacterial chromosome is transferred rather than only the F factor.

Recombination. In the mechanics of conjugation a bridge, or tube, is formed between the reacting cells, and the chromosome, including the sex factor, is transferred linearly. The entire process is complete in 90 to 100 minutes. If it is interrupted, as by agitation of the bacterial suspension in a blender, transfer is only partial, and even without agitation transfer is usually incomplete. When chromosome transfer is effected, the markers are transferred in precisely the same linear sequence from all mating cells, the origin of the sequence being the point at which the F factor is integrated with the chromosome. When transfer is incomplete, the frequency of transmission of markers is a function of their distance from the point of origin, and the sex factor is transferred last. Thus the bacterial chromosome may be mapped as a linear sequence of genes. The transferred markers are the result of recombination between the Hfr chromosome, or chromosome fragment, and the chromosome of the F- recipient cell. The information contained in the individual gene, or genetic element (see below), so transferred is a function of the sequence of purine and pyrimidine bases making up the nucleic acid chain. The coding of genetic information in this way has been described earlier (Chap. Five).

A number of terms have been coined for definition of the various spatial relationships. A recon is a unit of nucleic acid not subdivisible in recombination, and consists of about 12 nucleotide pairs. A muton is the shortest length of the nucleotide chain which must be altered to produce a mutant, a maximum of about five nucleotide pairs. Finally, a cistron is the unit of length, about 4000 nucleotide pairs, required to produce some kind of integrated function, but function can be impaired by mutations at many different locations on a cistron.

As has been pointed out earlier (Chap. Three), it is highly probable that the bacterial chromosome, at least in K-12 coliform

variants, is circular, and its linear transfer during conjugation involves breakage. In Hfr cells, breakage appears to occur at the point at which the F factor is inserted into the chromosome. It would seem necessary, too, that the Hfr chromosome be in contact with the outer portions of the bacterial cell to be available for transfer to the recipient cell. Such contact is with mesosomes, invaginations of the cytoplasmic membrane, and the point of contact is the locus of the sex factor. Conjugation probably involves appropriate receptor sites, or their equivalent, and the inhibition of mating by periodate through temporary destruction of the virility of F+ cells suggests that some surface polysaccharide-containing substance is involved.96 Presumably contact with the recipient cell initiates formation of the connecting tube, and triggers the transfer of the broken chromosome. The actual implementation of the transfer is not clear; it has been suggested that chromosome replication occurs concurrently with transfer, the force of replication providing for the transfer, and also that replication occurs prior to transfer but before the linear chromosome assumes circular form.

The separation of the F factor from an integrated position in the chromosome to assume autonomous character as in the F+cell is considered to be a result of crossing over. This is supported by the occurrence of variant autonomous F factors which include genetic markers that are adjacent to it when it is integrated with the chromosome. Male cells containing such variant F factors are known as F' cells and are able to transfer such associated markers to F-cells to give recombinants.

While the foregoing has been worked out substantially in its entirety by study of variants of the K-12 strain of E. coli, there is sufficient homology with certain other enteric bacilli to allow recombination across "species" lines. Recombination between Escherichia and Shigella and between Escherichia and Salmonella117 is now well established. Utilization of the former has been particularly informative with respect to the virulence of Sh. flexneri and has made possible the development of appropriate hybrids as immunizing agents (Chap. Twenty-two). At the same time, it is by no means certain the extent to which such findings can be extrapolated to other kinds of bacteria.

Viral recombination.²⁶ It is of particular interest that recombination occurs between variant or closely related strains of viruses, in that these agents appear to be genetic mechanisms uncomplicated by an associated physiological system.

Recombination between viruses occurs when sufficiently closely related strains or variants are "grown" together as mixed infections of the same host cell. As pointed out elsewhere (Chap. Four), mixed infection rather than interference is produced under appropriate experimental conditions. The progeny resulting from such mixed infections are quite analogous to those produced by bacterial recombination, i.e., types appear that are combinations as well as replications of the strains making up the inoculum. The observation that lysogenicity, i.e., apparently latent infection of the bacterial cell with temperate strains of bacterial virus, also behaves as a stable genetic character in recombination experiments with K-12 and B coliform bacilli and the λ coliphage serves to link the phenomenon of recombination with that of transduction (see below).

There seems to be no morphological aspect of viral recombination in that the mature virus particle does not exist during active multiplication within the host cell, and conjugation of vegetative virus resolves to an interaction between two kinds of viral nucleic acid. The nature of the exchange of hereditary elements is best understood for certain of the bacterial viruses, using markers. such as minute plaque formation, ultraviolet sensitivity, host specificity, and rapidity of lysis. Among these viruses the "mating" that gives rise to recombinants is, in effect, multiple in that the primary redistribution of genetic material is followed by other matings between recombinants and thus resembles recombination between populations rather than individuals. The occurrence of such successive matings is indicated by the appearance of progeny which could not have been formed by any kind of exchange between the two parental viruses.14

Analogous recombination occurs among several of the animal viruses.^{55, 83} The markers are characters such as pathogenicity for the mouse lung and the embryonated hen's egg, neurotropism, plaque morphology,¹⁰⁶ and antigenicity. The results of recombination experiments have shown, not only that recombinants occur, but that there

والمربيب

are linkage groups, as for example between mouse lung pathogenicity and antigenic character, and, further, that noninfectious virus inactivated by ultraviolet irradiation may enter into combination with infective virus. This last is suggestive of the transformation phenomenon (see below), possibly implying that the latter may be a special case of the recombination phenomenon. Recombination with the production of hybrids also occurs among the poxviruses and between antigenic types of poliovirus.³¹

TRANSDUCTION (TRANSFECTION)^{21, 62, 66}

The method of transfer of genetic material from one cell to another based on a sexual system and involving recombination of entire blocks of genes in intact cells is the conventional one in that it is shared by all kinds of living organisms, including microorganisms. In addition to recombination, there occurs among the microorganisms a transfer of genetic fragments, mediated by bacterial viruses, or introduced into the cell directly as macromolecules of polymerized nucleic acid. In either case the process is one of transduction of genetic elements, but the term transduction has been applied to the phage-mediated transfer, while the direct application of nucleic acid has been called transformation, because it was first observed in the transformation of immunological types.

In phage-mediated transduction the genetic material is transferred from the donor cell to the recipient by bacteriophage. Virulent phage may act as a transducing agent under appropriate conditions, but most often the transduction is by temperate phage. The lysogenic donor cells containing the marker are broken down by induced phage lysis, recipient cells are infected, and the marker is present in those which survive by becoming lysogenic. This is studied in the most part as transduction between strains of a given bacterial species, or different species, but it also occurs, like conjugation, across generic lines, between coliform bacilli and dysentery bacilli.68

Two kinds of transduction are to be distinguished. The one, sometimes called gen-

eralized transduction, is casual in the sense that the fragment of donor cell genetic apparatus carrying the marker is injected into the recipient together with viral DNA, but is not a part of it. About three per million phage particles are transducing for the marker, or about one transducing particle for every 300 to 500 bacterial donor cells lysed, so that relatively few of the lysogenic recipients are found to contain the marker. It is characteristic of transduction that usually only a single marker is transduced because the transducing particle contains only a genetic fragment from the donor cell, but occasionally markers may be so closely linked that both occur in the same fragment.

The markers may be of various kinds. Variants may be isolated which are characterized by markers such as specific nutritive requirements, fermentative abilities, resistance to chemotherapeutic substances, or antigenicity. Lysis of the lysogenic variant is induced, as by treatment with ultraviolet light, and the marker characterizing the variant is transferred together with lysogenicity, to a susceptible strain of bacteria. In this way a drug-sensitive strain of bacteria may be made drug-resistant, or, by transduction of antigenicity, new serotypes may be created.

The essentially passive role of the bacterial virus is substantiated by the ability of ultraviolet-irradiated phage to transduce, e.g., infectivity is destroyed by radiation more rapidly than the transducing factor, and transduction may be accomplished without inducing lysogenicity in the recipient. The virus thus functions as only a carrier of genetic fragments resulting from the lysis of the donor cells, and as a means by which such fragments are introduced into the recipient cell. The fragment suffices to replace the homologous gene in the recipient, the exchange occurring quite soon after the fragment enters the cell, and the prior homologue does not reappear. Such homologous replacement, as for example of flagellar antigens of Salmonella, suggests an organized genetic system in the recipient bacterium but offers no clue as to how the homologues are associated prior to the elimination of one or the other.

The other kind of phage-mediated transduction derives from the intimate relation between prophage and the host bacterium in the lysogenic state. Although autonomous as an infectious particle, the temperate prophage becomes a part of the bacterial genetic apparatus, and the induction of lysogeny is, in effect, a transduction. In recombination experiments the prophage segregates as if it were a bacterial marker and, further, it may be transduced as prophage by another bacterial virus. The λ coliphage is linked with galactose fermentation, suggesting that in this case the phage may occupy a predetermined site in the bacterial genetic apparatus. The fact that lysogenicity may be multiple, to as many as three different prophages, shows, however, that more than one site may be occupied by prophage. It has been suggested that the genic factors so imposed on the genetic apparatus of the host cell are not always a part of that apparatus and may be regarded as episomes.⁵⁰

Changes correlated with lysogenic conversion differ from those of generalized transduction in that they are present in all, rather than a small portion, of the lysogenic progeny and cannot be dissociated from the presence of prophage. The most interesting of these is the toxigenicity of lysogenic diphtheria bacilli.

It appears to be definitely established that all toxigenic diphtheria bacilli are lysogenic, though all lysogenic strains are not necessarily toxigenic, and that the induction of toxicity is inseparable from phage. This phenomenon has been studied in detail^{10, 37, 38} and may be described briefly. When any strain of diphtheroid bacilli sensitive to phage β is made lysogenic, it invariably becomes toxigenic; when lysogenicity is lost toxigenicity disappears but may be induced again when the strain is again made lysogenic. Another strain of phage, y, differing in host range, produces lysogeny of sensitive strains of bacteria, but these are not toxigenic. Recombinants of β and γ prophages have been isolated, of which one, β' , has the host range of β but does not produce toxigenicity, while another, γ' , has the host range of γ and does produce toxigenicity. Further, bacterial strains doubly lysogenic for β and γ are toxigenic. Thus the prophages behave as if they were bacterial genes, with toxigenicity dominant, affecting the metabolic processes of the bacterium concerned with the production of the iron-deficient porphyrin complex that is diphtheria toxin.

TRANSFORMATION29, 98

Transformation is a transduction accomplished by direct treatment of the recipient cell with nucleic acid from the donor cell and thus relates to viral replication via infectious nucleic acid (Chap. Four). It was first observed with pneumococcus in experiments in which the immunological type, determined by the antigenicity of the polysaccharide capsular substance, was changed or transformed. It also occurs with respect to characters other than antigenicity on the one hand, but, in addition, is to distinguished from other kinds of immunological changes, such as those associated with the S-R dissociation, environmental modification of antigenicity such as the temporary repression of flagella and flagellar antigen formation in the presence of dilute phenol.

It was suggested by Theobald Smith and Reagh in 1904 that bacteria might be immunologically altered by residence in different hosts, although they were unable to demonstrate such changes, and much later, Holtman^{46, 47} showed that enteric bacilli could acquire the antigenic specificity of Forssman antigen by growth in the presence of this substance, the specificity persisting through 20 to 50 transplants of the modified bacilli. The latter probably accounts for the irregular occurrence of Forssman antigen in a variety of bacteria and the presence of Forssman antibody in presumably normal animals, such as rabbits, in which the antigen does not occur, as a consequence of infection with such bacteria.

The variation now known as transformation was described in 1928 by Griffith, who inoculated animals with avirulent R strains of pneumococci originally derived from, for example, type 1 pneumococcus, but no longer having type specificity, together with a killed vaccine of encapsulated, typespecific pneumococcus of another type, such as type 2. Following development of an infection, living virulent pneumococcus of the vaccine type, in this example type 2, were found, indicating that the R variant from type 1 had been converted, or transformed, to the S virulent encapsulated type 2, i.e., had acquired the ability to synthesize the type-specific capsular polysaccharide of the vaccine strain. This phenomenon was subsequently studied in detail by others,

especially Avery and his co-workers, and could be made to occur in vitro.

The transformation reaction. Transformation in vitro occurs in several distinct stages. There is first a preliminary period of growth in an appropriate medium (see below); second, a period during which transformable cells make their appearance, usually during the latter part of the logarithmic growth phase; third, a short period, perhaps 10 minutes, during which the transforming principle is taken up by the recipient cells; fourth, a longer period, 45 to 60 minutes, during which phenotypic expression of the transformation develops; and, last, the appearance of progeny of the transformed cells which show the acquired character and breed true indefinitely.

Transformation factors. There are three variables in this process. The first is the substance originating in the donor cells and transmitted to the recipient, the transforming principle or TP. This was first isolated from pneumococcus, and subsequently from other bacteria, as a highly polymerized deoxyribonucleic acid; depolymerization or small changes such as a minor amount of deamination result in inactivation. The material retains its activity during purification and fractionation, as in resin columns, and appears to have a molecular weight of about 700,000, though there is reason to believe that only a portion of the macromolecule is active. Only a fraction of the TP is irreversibly adsorbed by the treated recipient cells, and most of it can be washed off or decomposed by deoxyribonuclease without interfering with the transformation. Kinetic studies indicate that one molecule per recipient cell is sufficient to transform, but when TP is present in concentrations greater than 10 molecules per cell, the rate of transformation is less than the extrapolated rate, suggesting some kind of interference.

The second variable is known as the serum factor which is, of course, present in *in vivo* transformation, but which must be supplied in the medium when transformation occurs *in vitro*. This factor is differentiable by dialysis into two fractions. The dialyzable fraction is replaced by pyrophosphate, and the nondialyzable fraction by bovine serum albumin. The manner in which these factors function is unknown. In some kinds of transformation a third component of the serum factor, agglutinating antibody to the bacteria,

is required, but this is a special case in that it is required only in certain immunological transformations.

The third variable is the susceptibility of the recipient cells to the action of the transforming principle. As implied above, all the cells in a bacterial culture are not capable of accepting the transferring principle. Cells which are, are said to be competent, and competent cells appear later in the logarithmic growth of the usual culture. The proportion is not high, ranging from one to ten per thousand cells. They occur in peaks, and under some conditions these peaks occur periodically. The peak persists in time only 15 to 20 minutes and is apparently associated with maturation of the individual cell; the peaks and their periodicity are a result of a partial synchronization of cell division. Cell division may be approximately synchronized17 (Chap. Four), with increase in the proportion of competent cells to as much as 17 per cent. That competence is associated with a physiological state is indicated by the occurrence of transformation when TP is not present in the growth medium but on transfer of competent cells to a medium containing TP.50 Further, competent cells may be frozen and still retain competence for as long as six weeks, though viability may persist for 18 months when the cells are stored at -20° C.

Other transformations. Transformation is not limited to that of pneumococcal types but has been demonstrated for immunological character in Hemophilus, meningococcus, coliform bacilli, and Shigella. Characters other than antigenicity are transformable also, including such diverse properties as fermentative abilities and drug resistance. In fact, it may be supposed that almost any bacterial characteristic may be reproduced by transformation. Transformation may also occur across species, or even genera if the pneumococcus is to be regarded as so separated from the streptococci, for streptomycin resistance has been exchanged between these microorganisms, in both directions via soluble DNA.

Fibroma-myxoma.⁵⁶ A closely similar, if not basically identical, phenomenon was described in 1936 by Berry and Dedrick, and is known as the Berry-Dedrick phenomenon or as the fibroma-myxoma virus transformation. The fibroma and myxoma viruses are tumor viruses infecting the rabbit, and be-

MUTATION 243

long to the pox group (Chap. Thirty-seven). The former produces a benign, localized tumor which begins to regress within a few days, while the latter produces a fulminating rapidly fatal infection. The transformation was originally described in substantially the way Dawson described type transformation of pneumococcus in vivo. Myxoma virus may also be transformed into fibroma virus in tissue culture. The transforming principle is effective not only as a heat-inactivated, DNAse-resistant preparation of fibroma virus, which electron micrographs indicate

to be vegetative virus, but also as a ureasolubilized preparation which is sensitive to DNAse.

There is evidence that this phenomenon may be a general one, at least among the poxviruses, for Japanese workers have reported similar transformations in tissue culture of myxoma virus into vaccinia virus and ectromelia (mousepox) virus, and of ectromelia virus into vaccinia virus. ⁴¹ In a general sense such transformations involve the possible integration of viral nucleic acid in the genome of animal cells.⁵⁹

The Nature of Microbial Variations

It is clear from any consideration of microbial variation that all, or nearly all, of the characteristics made use of in the differentiation and identification of these forms are subject to alteration. While many of them do not yet have counterparts in classic genetics built around differentiated higher organisms, there is no reason to believe that other than substantially the same mechanisms are operative for all living things.

At the same time, studies of microbial variation have broadened tremendously concepts of genetic mechanisms, and it has become clear that variability need not be the random process of selection of the fittest among spontaneously arising genic mutants, but may, in fact, be induced in the broad sense. The facility with which inductive or seemingly inductive changes may occur is possibly related to the more intimate association of the germ cell of the microorganism with environmental influences as contrasted with the protection of the barrier of somatic cells intervening between the environment and germ cells of higher forms.

Further, the concept of virus as an independent gene or group of genes, tentatively suggested much earlier, tends to be substantiated with the demonstration of situations, such as lysogeny, in which it becomes difficult to formulate definitions of virus and gene which are mutually exclusive. It is equally significant that parasitism is here extended to a genic level with extinction of the autonomy of the two agents.

It may be taken as fully established that the differential characters of microorganisms are the phenotypic expression of the func-

tioning of a genetic apparatus whose component parts behave as discrete entities, which may or may not be linked, and thus have the attributes of genes of classic genetics. It is equally well established that many differential characters depend, at least for their expression, on the presence of a specific substrate or other inducer in the environment. The question at hand is that of determining which of these mechanisms, or modifications of them, are altered with the appearance of microbial variants, and their relative importance in the phenomena of microbial variation. In general, there is a tendency to subordinate one or the other, and to take the view either that genic mutation is relatively all-important or that the great majority of microbial variants represent an adaptation in the sense of a response to environmental induction.

MUTATION13, 49

It is already apparent from foregoing considerations that genic changes may be induced in microorganisms in the phenomenon of transduction, either phage-mediated or direct as in transformation. The definition of mutation must inevitably be broadened from its classic conventional meaning to include these kinds of induced genic modification. So it is not a matter of whether genic changes occur, but rather one of, first, whether spontaneous undirected mutations occur and, second, the extent to which microbial variants represent a result of this process.

Spontaneous mutation. Randomness is

the identifying characteristic of spontaneous mutation in that the mutation occurs as a result of the operation of an indefinitely large number of small independent causes rather than one, or at the most a few large and important causes. The necessity for studying microorganisms as populations requires that a spontaneous mutant be selected so that it may become predominant and characterize the population in order to be detectable. It is an unfortunate consequence of this that a selective environment, whose selectivity is dependent upon the presence of a substrate or other potential inducer, is interposed at one point or another. The occurrence of spontaneous mutation must be inferred from population behavior* and cannot be of an unequivocal nature, but when such evidence is derived in different ways, its cumulative weight becomes great.

Many bacterial variations behave as if they were a consequence of spontaneous mutation, and the mutants selected, rather than induced, by the culture medium. For instance, the frequency with which variants appear is of the same order as the mutation rates established in higher forms, e.g., one variant cell per 10^6 to 10^9 parent cells. This rate may be increased by treatment with radiation or other mutagenic agents such as nitrogen mustards (β -chloroethylamines), though not with colchicine. These variants breed true, in fact could not be found if they did not, and behave in recombination experiments as genic entities.

If such variants occur spontaneously, it follows that their number is directly related to the size of the population, and in small populations would fluctuate widely. This consideration is the basis of the fluctuation test in which a parent population sufficiently large to contain some mutant cells is divided into many small parts which are grown independently. If only an occasional mutant is present in the parent population not exposed to the selective environment, its appearance in subcultures in the selective medium should fluctuate erratically rather than appear uniformly. Many microbial variants do show such fluctuation. The criticism that the fluctuation test shows only randomness, not necessarily spontaneous mutation, is, of course, a legitimate one.

A more direct method of demonstrating the occurrence of mutation in the absence of possible inducing substrates, i.e., preexistence of the mutant relative to its contact with the selective environment, is the replicate plating method. A plate culture on a nonselective medium is allowed to grow for a short time to produce microcolonies. The growth is then impressed on the surface of sterile velveteen, and the pattern of growth is imprinted on plates of selective mediums. Following incubation the growth patterns and the colonies on a selective medium, as for example one containing an antimicrobial substance, are compared, and if the colonial growth on the selective medium corresponds to that on the nonselective medium, it is inferred that the variant clone was pre-existing with respect to the selective agent.

Furthermore, the occurrence of conjugation among the microorganisms with consequent recombination of markers shows that such markers, gene-controlled enzyme systems, 69, 86, 115 segregate in a manner completely consistent with the occurrence of their determinants in a linear arrangement. Too, as indicated earlier, the process of transfer of genic material during conjugation may be interrupted to show a sequence in the markers transmitted. In consequence, it has been possible to prepare maps of gene loci for bacterial viruses as well as bacteria, but the necessary detailed information is not as yet available for the animal viruses.

The cumulative weight of this kind of evidence is considerable, and is regarded by many as establishing beyond reasonable doubt the selection of spontaneous mutants as the basis of the great bulk of microbial variations.

Its application to the phenomenon of drug resistance may be taken as a representative example. Suppose Bacillus X is adapted to grow in the presence of an antimicrobial agent in concentrations which inhibit the growth of the parent strain. The nature of the resistance, e.g., the development of alternate metabolic pathways, decomposition of the drug, etc., is, of course, irrelevant here. The process of adaptation is conceived as the spontaneous appearance in the parent population of resistant mutants which grow in the concentration of the drug applied while the parent strain does not. Resistance may be increased, as described earlier, by

^{*}For a detailed discussion of the relevant statistical theory see references 6 and 7.

cultivation of the variant in successively higher concentrations, and in each of these new mutants appear spontaneously which are characterized by an even greater drug resistance until some maximum is reached. This is the stepwise rather than uniform rate of emergence of resistance which is regarded as additional evidence of the spontaneous, rather than induced, appearance of resistant mutants.

On continued culture in the absence of the drug, resistance disappears gradually at about the same rate that it was acquired, and this is interpreted as a consequence of a series of back mutations to sensitivity to the drug.

INDUCED ADAPTATION

The wide range over which microbial adaptation occurs, and the specificity of the adaptations, has suggested to many workers that the adaptive process is a directed one rather than a chance occurrence, that is to say, is induced by the chemical character of the environment, rather than a consequence of the selection by the environment of spontaneously occurring variants. Further, the usual dependence upon the presence of the substance toward which the adaptation is directed suggests that the relation between the two is causal rather than coincidental. There is no question that specific induction occurs in the phenomenon of enzyme adaptation described earlier, and it is established that the synthesis of enzyme is specifically induced, at least in the sense of being markedly stimulated, in the presence of the substrate. The theoretical aspects of this phenomenon, upon which any generalization is dependent, have been examined by Yudkin¹¹⁶ who has formulated the concentration relationships of enzyme and substrate in mass action form. This approach has been further elaborated by Mandelstam,70 and shown to fit closely with the observed behavior of these systems.

The physiological processes of the metabolizing cell may be regarded as a series of interrelated reactions in which the product of one is the substrate of another, as in the catalysis of respiration. Or the linkage may be cyclical, one of the later reactions in the sequence providing an intermediate functioning in one of the earlier reactions in

conjunction with some other substrate, as in the cyclical processes of carbohydrate metabolism such as the alcoholic fermentation and the Krebs cycle. The individual reactions are determined by the concentration of intermediates, the amount of enzyme, and the reaction velocities.

Enzyme balance. If the kinds and proportions of enzymes present within the cell are affected by the nature and concentration of substrates present, adaptation can consist of an adjustment of the cellular physiology as a whole to utilization of the substrates with maximum efficiency. This is, in effect, a generalization of the phenomenon of enzyme adaptation and has been most fully developed by Hinshelwood.45 From this point of view, the sequence of metabolic events can be visualized as follows. A steady state occurs during logarithmic growth, but with the exhaustion of food materials, accumulation of metabolic products and the like, there is cessation of the maximum growth rate, concentrations of diffusible intermediates fall, and the individual enzymes decay and alter in their relative proportions as the system moves toward a new equilibrium. On transfer to fresh medium, readjustment is initiated during the lag period with the building up of concentrations of intermediates and a synthesis of enzymes in a shift toward an equilibrium consistent with maximum growth rate. Thus, the relative proportions of the elements of the catalytic system and the concentrations of substrates of the individual reactions exist in a series of metastable states of enzyme balance under ordinary culture conditions.

There is a great deal of evidence that alterations of this kind occur. For example, the formation of bacterial deaminases is suppressed during rapid growth in the presence of fermentable carbohydrate and does not occur at acid reactions but decarboxylases are formed at an acid reaction, and both kinds of enzymes are formed in the later stages of culture growth; the kind and proportion of enzymes present are a function of the age and condition of the culture. Similarly, the products of carbohydrate metabolism depend upon environmental factors, again a matter of balance in the function of the cellular enzymes.

If a strain of bacteria is transplanted to a medium differing from the one in which it has been grown, a greater degree of adjustment occurs. For instance, coliform bacilli ferment both glucose and lactose, but if cultured continuously on glucose and then transferred to lactose, the growth rate, measured as the mean generation time, is reduced. After several transfers in lactose the rate increases, and the strain grows as rapidly in lactose as it formerly did in glucose. If the training to lactose is only partial, reversion occurs in nonlactose-containing mediums, but if the strain has been carried through many transplants in lactose, the ability to use the sugar with a maximum efficiency persists. Since the bacterium ferments both sugars with facility the adaptation is not overt, but it is, nevertheless, a typical adaptation, and the result is clearly a consequence of alteration in the balance of enzymes already existing in the cell. The adaptive process is much more striking, and less obviously a result of change in enzyme balance, when there is a great differential between the parent and adapted strains, as between no detectable acidity and an active fermentation, whether it occurs slowly on successive transfer or very rapidly as in the formation of an adaptive enzyme.

The change in enzyme balance may be quantitative in nature. The enzyme in question may be present only as a precursor, the formation of enzyme occurring in the presence of substrate through mass action as suggested for adaptive enzyme formation. Or the enzyme may be initially present in only very small amount, but it has a high turnover rate. Or, finally, catalysis of the new reaction may be a function of an existing enzyme but at a relatively low reaction velocity, and adaptation a matter of expansion of that enzyme. The last opens the question of qualitative modification of the enzyme, in that distortion of its specificity by a slightly different substrate requires greater activation energy and hence a lowered reaction rate, but if the substrate is present during formation of the enzyme, and the distortion not too great, a modified pattern might eventually result.

Returning to the example of the development of drug resistance by microorganisms it is as satisfactorily accounted for on the basis of an adjustment of bacterial enzyme systems as on that of a stepwise selection of resistant mutants, and here the nature of the resistance becomes significant. As indicated earlier, drug resistance may result from the production of an inhibitor such as p-aminobenzoic acid in excess amounts, a qualitative modification such that the drug displaces the antagonist as an essential metabolite, or by diversion to an alternate metabolic pathway. The first of these is clearly an expansion of an existing catalytic system. Regarding the second, suppose it be assumed that the drug displaces the prosthetic group of an enzyme, viz., pantolyltaurine, to give a modified enzyme and the formation of different metabolic products. The adaptation can thus consist of an altered enzyme balance to allow the metabolism of the new intermediates, and, when this is established, the original essential metabolite competitively inhibits the new system, and the drug has become an essential metabolite. The development of an alternate metabolic pathway is likewise an expansion of an existing enzyme or system of enzymes which ordinarily contributes in but small amount to the maintenance of the concentration of a given intermediate, perhaps because of lower reaction velocity. When the function of the usual system is inhibited by the drug, the alternate is expanded, perhaps only quantitatively, to neutralize the effects of the lower reaction velocity. The whole is analogous to an industrial system in which a raw material for a given process is shut off, an alternative, more expensive, process is developed, and the economies effected in large-scale operation make it as efficient as the original process.

There is considerable evidence in support of the view that the development of drug resistance is intimately related to the presence of the antibacterial substance which functions to distort metabolic processes^{92, 94} as well as to serve as a selective element in the environment. For example, resistance may develop in the presence of concentrations of the drug too small to inhibit growth, or the rate of development of resistance may depend upon the way in which the microorganism is exposed to it or be too rapid to be accounted for by selection of spontaneous mutants. Such evidence, too detailed for presentation here, is not only consistent with a relatively rapid adjustment of the bacterial enzyme systems to the new circumstances, but in some cases

hardly admits a different interpretation.^{28, 114} Similarly, the acquisition of drug resistance by viruses, as in the case of picornaviruses and guanidine described above, is difficult to account for on other than an induction basis against the background of the nature of viral replication.⁵⁴

Induction versus mutation. There is probably little or no justification for regarding specifically induced microbial variation as completely apart from, and competitive with, variation arising as a consequence of alteration in the genetic apparatus of the microorganism. Conversely, it is untenable to account for all microbial variations other than adaptive enzyme formation on a basis of spontaneous genic mutation and selection. Rather, it is self-evident that the observed variant is the phenotypic, and therefore environmentally dependent, expression of the microbial genotype.

In relatively few instances, notably that of the β -galactosidase-permease system of mutabile strains of coliform bacilli described earlier, can these be sharply distinguished. In the great majority of microbial variations the distinction is not clear, leading to uncertainty as to the nature, or more precisely the relative importance, of the mechanisms operative in the production of the observed variant. The induced variations combine with genic mutation to increase

the adaptability of the microorganism substantially beyond the limited range imposed by a one-to-one or similar relation between genic unit or subunit subject to spontaneous mutation and the production of, say, a given enzyme. By their occurrence, the induced variations make unnecessary the postulation of improbably complex polygenic controls.

The lack of clarity of distinction goes beyond that of interpretation of a given variation for, on the one hand, genic modification can be induced in the transduction reactions, and, on the other, metabolic sequences may behave in a unitary way suggestive of a genic nature. In connection with this last, Pollock80 has suggested that chain reactions controlled by adaptive enzymes may be cyclic in that the end product and the starting material are identical. Such self-reproducing biochemical cycles, or "genocycles," may well have some degree of autonomy at a subcellular level, with single unit cycles showing the characteristics of genes, and multiple unit cycles that of linked genic characters. Further, such a view includes the possibility of variation arising from intracellular competition between cycles through diversion of a component of one cycle to another or even the initiation of new cycles by rearrangement to give the appearance of genic mutation.

Microbial Phylogeny

Among the microorganisms, as among other living things, phylogenetic or evolutionary relationships are inferred from existing, *i.e.*, persisting, forms. At one time it was thought that bacteria were the first forms of life because only the autotrophic bacteria could live in an inorganic environment. It is hardly likely that a complete, highly organized cell, containing complex catalytic systems and having the broadest synthetic powers, could have appeared *de novo* in an inorganic world.

There is now excellent reason to believe that a chemical evolution, resulting in the appearance of organic matter, antedated the origin of life.^{12, 34, 76, 104} It was suggested by Haldane in 1926 that amino acids and heterocyclic compounds found in proto-

plasm could have been formed from single carbon compounds such as formaldehyde under the influence of solar ultraviolet light. The indicated experiments have been carried out by many workers and have shown that such organic compounds may be formed in this way. Some years later Oparin suggested that carbon was initially in the form of metallic carbide which, on contact with water, formed acetylene, and polymerization of the acetylene, catalyzed by mineral substances, could have resulted in the formation of long-chain carbon compounds which may, in turn, serve as precursors of the kinds of molecules found in living protoplasm. A third possibility is that of the formation of organic molecules from inorganic substrates under the influence

of high energy radiation, and this has also been substantiated by experiment. Finally, electrical discharges in the presence of substances such as methane, hydrogen, ammonia, and water, i.e., under reducing conditions, result in the appearance of a variety of compounds, particularly of the amino acid type; these reactions too are demonstrable in the laboratory. The appearance of such substances through any or all of these means is necessarily a random process, but as soon as a substance occurs that has catalytic activity, an element of selectivity appears, and a plausible case may be made for, for example, the chemical evolution of the iron porphyrin compounds. 16, 73

Presumably toward the end of this period of chemical evolution, self-reproducing substances appeared to constitute the beginning of the phenomena uniquely associated with life. It has been suggested by Haekel, Oparin, and more recently Salser,88 that the occurrence of autonomous biochemical cycles, perhaps analogous to the phenomenon of enzyme adaptation, preceded the development of the coding mechanism of replicating nucleic acids. It has been objected that a nucleic acid system is, in fact, not only a necessary, but a much more probable primitive system,74 especially in view of recent information on the formation of nucleotide chains in the absence of the living cell. However this may be, it is likely that the bacteria and blue-green algae were among the first forms of life organized on a cellular level. Of existing physiological types of bucteria, the facultative anaerobic free-living heterotroph would appear to most nearly resemble an ancestral form from which four main lines of divergence to more highly specialized forms may be distinguished.

A relative scarcity of metabolizable organic substrate would favor the evolution of the autotrophs, and these may have differentiated quite early, first as the facultative autotrophs and then the obligate autotrophs. The facultative autotrophs are characterized by a relative flexibility in their requirements for oxidizable substrate and retain to some degree the ability to respire anaerobically. The sulfur bacteria, oxidizing compounds of sulfur ranging from hydrogen sulfide to polythionates and able to live anaerobically

in the presence of nitrate, are representative of the group. Such bacteria may be regarded as transitional forms in the phylogenetic sense, giving rise on the one hand to the pigmented photosynthetic sulfur bacteria, and on the other to the obligate aerobic obligate autotrophic bacteria such as the nitrifying bacteria restricted to the oxidation of ammonia to nitrite or nitrite to nitrate.

Two lines of divergence occur with respect to the utilization of gaseous oxygen. One of them is that of the obligate anaerobes. highly specialized free-living heterotrophs closely adapted to living in the absence of oxygen, which lack a portion of the respiratory catalytic system, and characterized by unusual energy-yielding reactions such as the oxidation-reduction of paired amino acids and the metabolism of lactic acid to compounds such as butyl alcohol and acetone. The other line is that of the obligate aerobes which grow poorly or not at all in the absence of molecular oxygen, since they lack the ability to reduce many substances other than oxygen in the oxidation-reduction reactions of respiration.

The parasitic and pathogenic microorganisms may have been derived from these three groups of free-living heterotrophic bacteria. It is probable that toxigenicity in the broad sense is a prerequisite to the evolutionary development of the parasite in that it represents the entering wedge to invasion through deleterious effects on the integrity of the host tissues. The formation of potent toxins by certain of the free-living heterotrophs such as the botulinus bacilli, and the limited invasive powers of highly toxigenic bacteria such as the tetanus bacillus. suggest that they are forms which, though toxigenic, are not yet, or are only poorly, adapted parasites in that they are unable to invade the host tissues and set up a sufficiently mild infection so that they may persist in the host.

There appears to be little question that the host-parasite relation has markedly affected the microorganisms that became parasitic and contributed significantly to their phylogenetic differentiation. ¹⁰¹ For the most part, such effects are inferred from existing kinds of microorganisms and the diseases they produce, but in the case of syphilis the relative mildness of the modern disease as contrasted with its severity in

the early sixteenth century has been taken by some to be indicative of a reduced virulence of the spirochete for man.

If it be assumed that an important factor in the survival of the parasite is the extent to which it achieves a relatively innocuous but persisting infection in the host, from the microbial point of view the microorganism that produces a highly fatal disease may be said to have failed. It must be noted in this connection, however, that the causative agents of highly fatal diseases of man are not necessarily evolutionary failures; the high fatality of certain rickettsial diseases such as spotted fever, for example, is a consequence of adaptation to a host other than man, in this case the arthropod which is the vector from the anthropocentric point of view. To the microorganism the arthropod is the host, and human infection is an inconsequential episode in its life history.

The adaptation of the microorganism to the tissues of the host may be accompanied by an increasing dependence upon the host. Varying degrees of dependence are clearly evident as the generally fastidious nutritive requirements of the parasitic microorganisms and by host, and even tissue, specificities. In the first instance most pathogenic bacteria that occur within the host tissue proper require a relatively rich culture medium for growth and are often significantly altered by cultivation in vitro, as shown by loss of ability to invade the host. less exacting nutritive requirements, etc., as described earlier. Still others, such as the syphilis spirochete and the leprosy bacillus, have not been cultivated in vitro, and the rickettsiae and viruses are distinguished by their requirement for a living cell substrate for growth and a lack of other than token independent metabolic activity at the most. While the viruses are thought by some to be extremely primitive microorganisms, it is generally believed that they are degenerated forms occurring in continuous series from the rickettsiae, which serve as a connecting link to the bacteria, through the agents of the psittacosis-lymphogranuloma group, to the larger viruses of the pox group, and culminating in the viruses consisting only of nucleoprotein.4

In the second instance, a microorganism may be well adapted to some kinds of tissue but not to others. For example, the meningococcus occurs widely in the upper respiratory tract of man and is restricted to the human host, but when it invades the central nervous system, it produces a highly fatal disease. Similarly, infection with poliomyelitis virus is very common and confined to man, but only in the rare individual does it damage the host to give symptoms of the disease. The green streptococci are universally present in the mouth and upper respiratory tract of man, and their presence is regarded as "normal," but when they infect the valves of the heart, the subacute bacterial endocarditis produced is a highly fatal, though rare, disease. In effect, infection may be widespread but not overtly apparent, with actual disease occurring only rarely. Such a microorganism is a welladapted parasite and is subjected only rarely to the unfortunate happenstance of causing fatal disease.19

The extent to which the microbial variations are significant factors in a general pattern of evolutionary differentiation and specialization of microorganisms is a matter of speculation, but no more so than the role of classic genetics in the evolution of higher forms. At the same time, such variations are an important factor in the finer distinctions between microorganisms. Microbial phylogeny may be inferred with respect to broad tendencies and groups of microorganisms but apparently does not penetrate to the levels ascribed to microbial genus and species. For instance, when the antigenic structure of bacilli of the Salmonella group began to be precisely defined, a number of "trees" purporting to show a phylogenetic relationship among the antigenically different types were constructed. This is no longer of any interest because it has become clear that such types may be shown to occur by transduction and recombination, and it is highly probable that antigenic types are produced in nature in this way, particularly by phage-mediated transduction. From the phylogenetic point of view, the fertility groups, rather than subdivisions of them, are the important element, but as yet these are poorly understood.

THE TAXONOMY OF **MICROORGANISMS**

Of the microorganisms, the fungi are clearly plants and the animal parasites are unicellular and multicellular animals, and both groups are formally classified on the conventional morphological basis as described elsewhere (Chaps. Thirty-two and Thirty-four). The bacteria and viruses occupy an intermediate position between the plant and animal kingdoms. They are linked to the fungi through the actinomyces and plant-like bacteria, especially the mycobacteria (tubercle and related bacilli) and the corvnebacteria (diphtheria and diphtheroid bacilli). Their relation to the animal kingdom through the protozoa is less clear. though the spirochetes are considered by many to be more animal-like than other bacteria. The rickettsiae and viruses are perhaps best regarded as offshoots of the bacteria and related to the plants and animals proper only through the bacteria.

Since the bacteria have properties of both plants and animals, at one time the question of whether they should be allocated to one kingdom or the other was an active one. An alternative proposal that gained some support, but not acceptance, was the creation of a new third kingdom, the Protista, for these forms. In time it became apparent that this question is irrelevant in the sense that an unequivocal answer to it serves no useful purpose, and the whole matter has been largely dropped from active consideration. Relatively early, however, the opinion prevailed that, in spite of the occurrence of both plant-like and animal-like properties among the bacteria, in total they resemble plants more than animals, and they were formally classified with the plants under Thallophyta as Schizomycetes, or fission fungi. The postulated relationship to other plant phyla is indicated in the accompanying outline. At the same time, the prominence of comparative physiology in the characterization and differentiation of the bacteria and the animal-like nature of their physiological processes leads many bacteriologists to think of them casually as animals and refer to them as "experimental animals." There is, of course, little or no basis for classification of the rickettsiae and viruses as plants, or animals either, for that matter.

Although the interrelationships of the organisms included under Schizomycetes present problems which are, in many essentials, new to the taxonomist, certain "natural" groups are apparent. Of these the most obvious is that based on morphology, with primary division into spherical, rod-

Phylum I. Thallophyta, plants without distinction of root, stem, and branch

Subphylum 1-the algae

Subphylum 2-the fungi-thallophytes lacking chlorophyll

Class I. Schizomycetes-the bacteria

Class II. Myxomycetes—the slime molds

Class III. Phycomycetes-the algae-like fungi

Class IV. Ascomycetes—the fungi which form ascospores Class V. Busidiomycetes—the fungi which form basidiospores

Phylum II. Bryophyta-the mosses

Phylum III. Pteridophyta-the ferns

Phylum IV. Spermatophyta-the seed-bearing plants

shaped, spiral, and filamentous forms, and subdivision on the basis of spore formation, presence and location of flagella, and staining reactions to the Gram and acid-fast stains. The earlier classifications, the better known of which are those of Migula and of Lehmann and Neumann, were made on this basis. These classifications exerted a strong influence on bacterial taxonomy and resulted in the naming of a great many species of bacteria, many of which persist.

Morphology is, however, not a sufficient basis for the separation of bacterial species, for many morphologically similar organisms may be quite different in other respects. Physiological differences, generally readily determinable in the laboratory, have been widely used. A number of workers are of the opinion that comparative physiology should constitute the primary basis of separation, rather than being subordinate to morphology.

Beyond such primary subdivisions, classification becomes increasingly difficult, and it is quite clear that this is so because not nearly enough is known of the phylogenetic relationships of the bacteria to one another for a detailed classification with definition of genera and species. This question has been discussed in some detail by van Niel,²³ who shows that as yet any classification can be little more than a key, and species are only "form" species, that is to say, no more than convenient handles.

The fundamental difficulty in preparing a classification rather than a differential key for the bacteria and viruses is a general uncertainty as to the significance or triviality of the differential characters used.6.10.19 Inevitably, a sound taxonomy will need to be based on microbial genetics and fertility systems, the latter in the broad sense to include the transduction reactions as well as sexual recombination. Still other approaches include the occurrence of key cellular constituents determinable by biochemical analysis; there is, for instance, some biochemical basis for Gram stain differentiation, evidence suggesting that content of amino acids and sugars, as determined by chromatography, and the purine and pyrimidine base ratios in microbial DNA show some correlation with genera and species, etc.

While the variability of microorganisms is significant to classification, it is not, as

might be supposed, a deterrent to differentiation and characterization by the usual physiological and immunological methods. Instability becomes evident when the environment is varied, but ordinarily microorganisms isolated in the same way retain their individuality for purposes of identification, or, if variation is common, as the O-D variation of influenza virus on primary isolation in the allantoic cavity of the embryonated hen's egg, it occurs with some regularity and is taken into consideration. Aberrant forms occur from time to time, of course, but in general an identification key is both practical and useful even though it may fail to represent genetic or other relationships.

Of the variety of formal classification systems prepared over the years, that of Bergey's Manual¹ has been the most detailed and has persisted, though it is not generally accepted. This, and other classifications have purported to be based upon phylogenetic relationships. It now seems to be generally, if tacitly, understood that microbial genera and species are no more than form genera and species. At the same time, there are practical problems of identification, as for diagnostic purposes, of some generally accepted common coinage of nomenclature. The former is recognized in the preparation of keys, such as that of Skerman²⁰ based on the Bergey classification, and those of Cowan^{4, 5} covering the pathogenic forms. The latter appears to be evolving in compromise form through the efforts of the International Association of Microbiological Societies.

Numerical taxonomy. 14, 21 With the general availability of computers, and the spreading conviction of the present futility of a phylogenetic classification of microorganisms, considerable interest has developed in numerical taxonomy. In general, unit characters are used and are not weighted, although complex characters broken down into units acquire an effective weighting. Such unit characters are necessarily derived from what are known as operational taxonomic units (OTU) which, in practice, are strains of microorganisms. Since no differentiation is made as to the relative "fundamental" importance of such unit characters, a classification derived from them is phenetic rather than phylogenetic. A relatively large number, not

Classification of Microorganisms According to Bergey (1957)

	THE STATE OF THE S	carron	of iviter outgains in According to Dergey (173)	s w mergey (1727)
ORDER	FAMILY	TRIBE	GENUS	
	Nitrobacteraceae		Nitrosocccus	The nitrifying bacteria

	Bacillaceae	Bacillus	Aerobic spore-forming bacilli such as B. anthracis and B. subtilis Obligate anaerobic spore-forming bacilli, including bacilli of tetanus, gaseous gangrene, and botulism
	Mycobacteriaceae	Mycobacterium	Tubercle bacilli, leprosy bacilli, saprophytic forms
Actinomycetales	Actinomycetaceae	NocardiaActinomyces	Aerobic, sometimes acid-fast actinomycetes Anaerobic actinomyces of actinomycosis
	Streptomycetaceae	Streptomyces	Soil forms, often producing antibiotics
Spirochaetales	Spirochaetaceae	Spirochaeta	Free-living forms Saprophytic water forms Parasite of molluscs
	Treponemataceae	BorreliaTreponema	Relapsing fever spirochetes Spirochetes of syphilis and yaws Spirochetes of infectious jaundice and field fever
Mycoplasmatales	Mycoplasmataceae	Mycoplasma	Pleuropneumonia-like organisms (PPLO)
	Rickettsieae	Rickettsia	Typhus fever, spotted fever, etc. Q fever
Rickettsiales	Kickettsiaceae Ehrlichieae	Cowdria	Heartwater disease of cattle
	Bartonellaceae	Bartonella	Bartonellosis of man Bartonellosis of dogs, rodents, and cattle
Virales			Viruses infecting bacteria, plants and animals

less than 50, of unit characters must be used to give reasonable confidence limits to the results. The use of many units gives a cross-section of the group so analyzed, and a general purpose classification which is polythenic in character. When fewer units are used for the development of special purpose classifications, *e.g.*, diagnostic keys, the classification tends to be monothetic. Such special purpose classifications may be derived from a general purpose classification.¹²

Following tabulation of the data, i.e., n character units as distributed among t operational units (OTU), similarity indices (S) are calculated for each pair of OTU's. A commonly used measure of similarity is a coefficient of association, $S = n_s/(n_s + n_d)$ when n_s is the number of similarities, and n_d the number of differences. Tables of S are normally triangular. Cluster analysis is carried out by forming taxonomic groups of OTU's which show the greatest similarities. These clusters are called phenoms, and may be arranged in diagrammatic form based on their similarities to one another. Such analysis can lead to the definition of a "mean organism" or most typical strain and this can be considered to be the neotype, for example, a neotype of Pseudomonas.11

Other methods of analysis may be used. Principal component analysis avoids the preparation of cluster diagrams, and differs in that it gathers characters into clusters and weights them.⁸ The use of probabilistic similarity indices is a somewhat more lengthy procedure, but also avoids the clustering procedure, and is said to provide finer subdivisions.⁷

Nomenclature.^{3, 9} Neither the botanical nor zoological codes of nomenclature have been satisfactorily applicable to the bacteria and viruses, and an official International Code of Nomenclature of Bacteria and Viruses has been, and continues to be, developed by committees appointed by the several International Congresses of Microbiology.

In general a bacterium has a generic name, always written with a capital letter, which may or may not be descriptive (for example, Bacillus—a small rod; or Pasteurella—in honor of Pasteur) and a specific name which may be an adjective (albus—white) or a noun indicating possession (Clostridium welchii—Welch's clostridium) or a noun in apposition (Bacillus radicicola—the root-

dweller bacillus). The practice of indicating the author of the name, as in Bacillus subtilis Cohn, is not as common in bacteriology as in zoology or botany. The use of trinomial and quadrinomial names such as Granulobacillus saccharobutyricus mobilis nonliquefaciens is obviously highly undesirable. Trinomials are occasionally useful in the designation of varieties of subspecies. Common names are, of course, used; terms such as Friedländer's bacillus and the typhoid bacillus are frequently encountered.

Genera. Perhaps one of the greatest difficulties the bacterial taxonomist labors under is the paucity of genera. The question of what degree of difference shall be judged sufficient to establish new genera is one to which there is as yet no satisfactory answer. At the present time considerable confusion and lack of uniformity still exist. In a number of instances new generic names have obtained wide currency among bacteriologists in many parts of the world, partly, doubtless, because they are applied to fairly distinct groups of microorganisms and have genuine classificatory value. Such are Brucella for the bacilli of undulant fever of man and contagious abortion of cattle, Salmonella for the paratyphoid bacilli, and Pasteurella for the bacilli of hemorrhagic septicemia in domestic animals and the bacilli of plague and tularemia; the name Shigella for the dysentery bacilli has gained a considerable degree of recognition. Nevertheless, the status of genera of bacteria, and viruses especially, is questionable in that they do not have the status of botanical and zoological genera based on character or gene frequencies and capacity for hybridization. The cross-fertility shown by recombination between Escherichia and Shigella and Salmonella referred to earlier (Chap. Seven) is a clear indication of the uncertainties in definitions of bacterial genera.

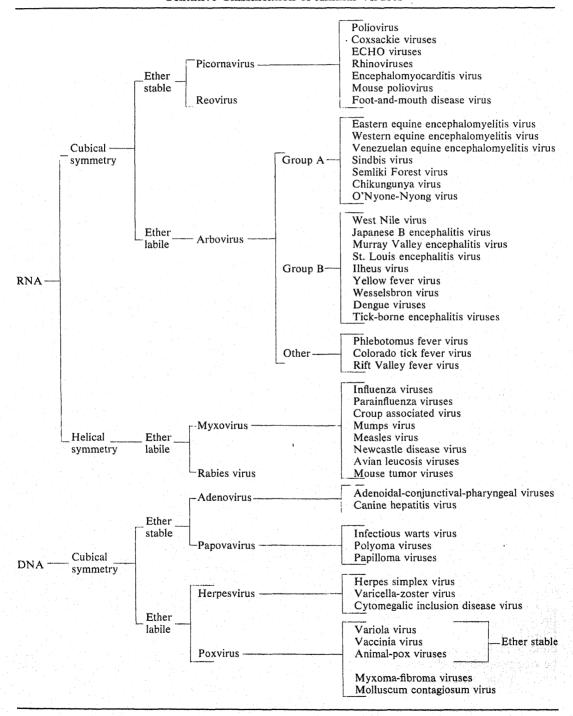

Species. 16 The differentiation of species is made for the most part on a physiological basis. A single character is hardly sufficient, particularly in view of the facility with which variation occurs. The use of a number of such characters is the rule, but difficulties are frequently encountered when intermediate forms occur. This is common among the enteric bacilli, possibly because these are better known than many groups of bacteria.

Types.² Immunological differentiation is generally regarded as not of species status though it may sometimes coincide with spe-

cies differentiation on a physiological basis. Conversely, minor cross-reactions between species are not indicative of species identity. There are some exceptions to the former, however, and many workers divide the genus Salmonella into species on the basis of antigenic structure. Immunological differences

are of very considerable value, particularly for epidemiological purposes, and are usually the basis of distinction of types within a species. Thus the streptococci are divided into groups, designated A, B, C, etc., on the basis of one kind of antigen, and into Arabic-numbered types within and across species by

Tentative Classification of Animal Viruses

another. The pneumococci are similarly divided into numbered types on the basis of capsular antigen. Clostridium botulinum is separated into types, A, B, C, etc., on the basis of the immunological specificity of the toxin, and these have no relation to the immunological character of the cell substance. There is, then, no general practice with respect to type differentiation. Physiological differences within species are usually not used to differentiate types, and the biochemical reaction is simply given as variable.

Classification of viruses. 13, 15, 24 While the classification of viruses presents problems to the taxonomist that are in many ways unique, the questions of characterization and nomenclature require answers. As in the case of the bacteria, a number of names have been evolved or suggested that have proved useful and generally acceptable. Terms such as poxvirus, poliovirus, and herpesvirus are simply a contraction. Others, such as adenovirus and rhinovirus were suggested as such. Still other names are descriptive terms for groups of viruses. The last includes reovirus as indicative of their respiratory-enteric origin, picornavirus meaning small (pico) RNA viruses, arbovirus (or arborvirus) to designate the arthropod-borne viruses, and papovaviruses for those of the papillomapolyoma group.

Dichotomous separations may be made on the basis of a number of characteristics. leading to definition of groups of viruses. A primary separation is effected on the basis of nucleic acid, i.e., into DNA and RNA viruses. Similarly, symmetry, helical or cubical, allows a second dichotomy. A further useful separation may be made with. respect to ether sensitivity, and may reflect a basic difference in lipid structure of viruses. The presence or absence of a limiting membrane, or envelope, makes possible still another dichotomy.17 More detailed characteristics, such as the diameter of the nucleocapsid of helical viruses and the number of the triangulation and number of capsomeres in the capsid of cubical viruses, have been suggested to allow further differentiation. 18

Separation into main groups, as shown in the accompanying diagram, seems to be both feasible and useful, and viruses whose nucleic acid type and symmetry have yet to be determined should fall into such a tentative schema. Whether or not elaboration to a detailed classification, necessarily requiring additional new and unfamiliar nomenclature, as has been proposed¹³ would be more confusing than revealing at the present time is not clear.

Chapter Nine

THE PATHOGENIC MICROORGANISMS AND DISEASE

Infectious disease may be regarded as a by-product, and not an inevitable one, of the host-parasite relationship. While, as suggested earlier, the initiation of the career of a parasitic microorganism may be based on its ability to produce sufficient damage to the host to facilitate the development of foci of infection, pathogenicity is incidental to the parasite and has significance only as it relates to the establishment of an ecological niche and to the survival of the microorganisms.

The etiological relation of microorganisms to infectious disease was suspected by some not long after their discovery by Leeuwenhoek and, in a sense, found support in Jenner's vaccination studies and those of others, especially the classic work of Snow on the transmission of cholera, in which a con-

tagium vivum was implied. It was not until past the middle of the nineteenth century that, as described elsewhere (Chap. One), this belief began to crystallize into knowledge through parallel developments such as the transmission of anthrax by infected blood by Brauell in 1867 and the recognition of the resemblance of fermentation processes to sepsis to provide the basis of Lister's antiseptic surgery, culminating in Koch's demonstration of the microbial etiology of anthrax. Through exploitation of his pure culture techniques in application to a wide variety of diseases, the etiology of many was resolved to displace the Hippocratic doctrine of imbalance of the four bodily humors-blood, phlegm, yellow bile, and black bile-as the basis of all disease.

The Specific Microbial Etiology of Infectious Disease

It is one thing to suspect, or even have some evidence of, the ability of microorganisms to produce disease and quite another to develop unequivocal proof of a specific etiological relation between a given microorganism and a given disease.

Koch's postulates. Such proof was first offered by Koch in the form of a logical chain of experimental evidence, usually known as Koch's postulates, although there is no evidence that they were so formulated by Koch, and good reason to believe that they originated with Koch's professor, Cohn. However this may be, there are four of these; a fifth was suggested at one time but it is usually not applicable.

The first postulate. The first of these is the observed occurrence of the microorganism in association with the disease. This is relatively simple in some diseases in which the causative microorganism is found in pure culture in some kinds of specimens, viz., the typhoid bacillus in the blood or the plague bacillus in fluid aspirated from the infected lymph nodes in the bubonic form of the disease. In others, however, notably infections of the respiratory and intestinal tracts, the causative microorganism occurs admixed with many other, often similar, forms and needs to be sorted out.

The requirement for such preliminary observation is self-evident in that if an associ-

ation were not observed there would be no reason to suspect an etiological relation requiring further investigation. At the same time, it is necessary to emphasize the first postulate for a number of reasons. First, closely similar, even indistinguishable, clinical syndromes may have quite different etiology. For instance, it is not possible to distinguish among certain diarrheal diseases of varied etiology on clinical grounds alone, e.g., acute bacillary dysentery and cholera occurring, as often is the case, in debilitated persons; a variety of bacteria may be the cause of urinary tract disease; and the problem of the etiology of the so-called common cold is largely a consequence of a wide variety of etiological agents which give rise to substantially the same symptoms.

Second, the term "observation" must be taken broadly. In the case of pathogenic bacteria there may be no morphological distinction between the pathogen and related nonpathogens, e.g., bacteria such as the diphtheria and diphtheroid bacilli and the pathogenic enteric bacilli and nonpathogenic coliforms are morphologically indistinguishable. Further, when the infectious agent is too small to be resolved in the light microscope, as is the case with the viruses, it cannot be directly observed. Thus the first postulate melts into the second in that characterization and differentiation of the microorganism in isolated form are often, in fact usually, required to establish its presence in association with the disease.

Finally, the first postulate has been taken to imply not only presence of the microorganism in association with the disease, but also the corollary that it is absent in the absence of disease. Quite aside from the occurrence of similar microorganisms in the same specimen, only one of which may be related to the disease, the pathogenic microorganisms may be present in individuals who have no symptoms of the disease, viz., inapparent casual infections, carriers, and other forms of asymptomatic infection. It was the presence of diphtheria bacilli in normal as well as diseased individuals that led Klebs, who discovered this microorganism, to question its etiological relation to the disease.

So, in practice, it is necessary to qualify the dogmatic first postulate in a number of ways, viz., observation must be stretched to include, for example, the cytopathology of tissue culture inoculated with infectious material, an observed association in at least a majority of cases of the disease, and regard microorganism as suspect even though it may be found in some healthy persons. Such association is by no means proof of an etiological relation, and further evidence is required.

The second postulate. The second postulate is that the microorganism must be isolated and grown in pure culture. This is clearly essential to effect a separation of the causative agent from other microorganisms when they are present and, as indicated above, is often an integral part of the first postulate for purposes of characterization of the agent. It is usually possible to isolate and grow in pure culture pathogenic bacteria, the practical difficulty being the requirement for an appropriate culture medium, but occasionally this cannot be done. The leprosy bacillus, regularly found in enormous numbers in material from lesions, is morphologically distinctive both in its acid-fast staining character and the arrangement of the individual cells but has not, despite perennial reports to the contrary, been cultivated in the laboratory, either in lifeless mediums or in tissue culture, nor has direct inoculation of leprous material been unequivocally successful. There is an immune response in the disease, manifested as a hypersensitivity to soluble material (lepromin) extractable from leprous nodules. This last is feeble supportive evidence because the hypersensitivity crosses with that to tuberculin, but the leprosy bacillus is provisionally accepted as the etiological agent of the disease, largely because there appears to be no alternative agent.

The spirochete of syphilis also has not been cultivated in compliance with the second postulate, but its etiological relation to the disease is more firmly established because supportive evidence is relatively strong. This includes a specific immune response to the spirochetal substance appearing during the course of the disease and the reproduction of the disease by direct inoculation of infectious material containing, so far as is known, only the spirochete. In some instances, then, the requirement of the second postulate may be circumvented with a greater or lesser degree of probability of the presumed etiological relation.

In the case of the rickettsiae and viruses,

isolation is necessarily growth in tissue culture or the embryonated hen's egg. It might be supposed that the purity of such cultures is questionable but, while this may be true to some extent, the occurrence of viruses in mixed culture in tissue culture is usually evident. Growth of these agents is directly demonstrable in the case of the rickettsiae. which may be seen in the light microscope. and indicated in the case of the viruses by appropriate, often characteristic, pathology of the tissue substrate, or some unique feature such as the development of hemagglutinin in the allantoic fluid of the embryonated hen's egg infected with viruses of the influenza group. In some instances, however, there may be no overt evidences of growth, and the agent may be carried by so-called "blind passage" in a series of tissue or egg cultures. After several such transplants cytopathic effects may become apparent, and in any case the material is tested for infectivity when the dilution is sufficient to rule out persisting infectivity. The somewhat devious nature of such procedures does not invalidate them.

The third postulate. The third postulate requires that the disease be reproduced in a susceptible animal by inoculation with the microorganism in pure culture. This is often difficult to accomplish for two reasons. First the disease must be reproduced in some recognizable form, i.e., will need to bear sufficient relation to the naturally occurring disease. Second, a susceptible animal may be difficult to find. These are not matters of great importance in the study of diseases of, for example, domestic animals, for the natural host may be the experimental host also. In the case of infectious diseases of man, however, some experimental animal must be found. The etiological agents of human disease are often closely adapted parasites, so much so that they will either not infect, or will not produce disease in an experimental animal that is recognizable as related to the naturally occurring human disease.

While in a general way certain of the monkeys and higher apes, such as chimpanzees, are more susceptible to infection with human pathogens than are, for example, rodents, susceptibility does not necessarily parallel phylogenetic relationships. The search for a suitable experimental animal becomes in large part a matter of trial and error and educated guess. In the 1930's, for instance, the only reasonably available experimental animal in which poliomyelitis could be reproduced was the rhesus monkey. One eminent investigator systematically inoculated all kinds of experimental animals that came to hand, and finally found that one strain of this virus could infect the cotton rat. Similarly, influenza could not be reproduced in experimental animals for many years until the similarity of the lesions of the lung produced in ferrets by distemper virus to those of human influenza was noted, and it was found that human influenza could be reproduced in the ferret by intranasal inoculation.

Other diseases of man, such as gonorrhea and typhoid fever, have not been reproduced in ordinary experimental animals, but some, such as tuberculosis and diphtheria in the guinea pig, are reproduced with facility. The mouse is exquisitely susceptible to infection with the pneumococcus on parenteral inoculation, and man appears to lie midway between the mouse and the more resistant dog with respect to susceptibility to infection with this bacterium. While there are many others, these examples suffice to illustrate the somewhat erratic occurrence of susceptibility to infection with the pathogenic microorganisms.

The importance of reproducing infectious disease in an experimental animal cannot be overestimated. Unless the disease can be studied under the controlled conditions of the laboratory it must remain inadequately understood. It is equally obvious that unless this third postulate is fulfilled it is not possible to fully establish the etiological relation of a given microorganism to a given disease.

The fourth postulate. According to the fourth postulate, the microorganism must be found in the infection produced in the susceptible animal, and shown to be the same as that inoculated. If the first three postulates are met, the fourth ordinarily follows without difficulty. It is nonetheless necessary to show that the animal was in fact infected with the microorganism and that the disease or death so produced is specific in that it is a consequence of that infection rather than some intercurrent infection of the experimental animal. Rarely there is some difficulty in this connection. Certain of the tumors of virus etiology, for example, are transmissible by cell-free filtrates, but after several passages by tissue implantation it may not be possible to find the virus. The reasons for this are relatively complex and, in part at least, are technical in nature.

The "fifth postulate." Following the discovery of the bacterial exotoxins, it was suggested that a fifth postulate, namely that the disease should be reproduced in susceptible animals by inoculation of the cell-free products of microbial growth, might be added. This is applicable in only a minority of cases and, while it lends support to the identification of the specific etiology of a disease, is not essential to establishing that etiology beyond reasonable doubt.

Supporting evidence. Less direct but supporting evidence for the etiology of a given disease assumes significance when the evidence provided by the four postulates is equivocal. This has been implied above in relation particularly to inability to reproduce human disease in characteristic form in experimental animals. The most important of such supportive evidence is immunological in nature. Taking the example of typhoid fever, and neglecting the accidental human infections with pure cultures of the typhoid bacillus which satisfy the requirements of the third postulate, immunological evidence strongly supports the etiological relation of the microorganism to the disease; the disease may be prevented by immunization with vaccines prepared from cultures of the microorganism, and the naturally infected individual who recovers from the disease develops an immunity directed specifically toward the microorganism which is demonstrable in a number of ways. Or the indirect supporting evidence may be epidemiological in nature, serving to pinpoint a particular microorganism with respect to a given disease even though the disease cannot be reproduced experimentally.

Multiple etiology. In naturally occurring disease more than one kind of microorganism may be concerned, and three kinds of such diseases may be distinguished. Under some conditions secondary infection is not uncommon, the primary invader serving to reduce the resistance of the host so that a second kind of microorganism, of limited pathogenic powers and often a part of the normal microbial flora of the host, may produce disease. Staphylococcal pneumonia, for instance, is usually not a primary infection but is found to occur most often as a secondary infection, commonly as a sequel

to influenza. Similarly, Proteus is of relatively limited pathogenic capabilities, but is potentiated by staphylococci, apparently a substance formed by staphylococci, so that it becomes a virulent, lethal agent.² Other kinds of diseases are characteristically mixed infections in that more than one kind of microorganism is concerned from the outset; thus, perhaps half a dozen species of bacteria are the causative agents of gaseous gangrene, occurring in various combinations but rarely alone. In both secondary and mixed infections the causative microorganisms are independent and individually capable of producing a disease condition.

The third kind of infection is that in which the etiological agent is not single but multiple, and the disease is a consequence of a synergistic relation between the microorganisms such that the combination has pathogenic capabilities that its components do not. Such multiple etiology becomes complex and is possibly more common than now appears. Two examples will suffice to illustrate it.

One is the now classic example of dual etiology of disease, that of swine influenza described by Shope. Here the two microorganisms are a porcine variety of the influenza bacillus, Hemophilus suis (H. influenzae var. suis), and a variety of the influenza virus. The disease swine influenza is not caused by either the virus alone or the bacterium alone. but only by a combination of the two. The other example is that of diphtheria of man. For 70-odd years there was no reason to believe that the microbial etiology of this disease was other than clearly and fully established. Not only was the diphtheria bacillus isolated and characterized in 1883, but the following year the powerful exotoxin of the microorganism, capable of producing the disease symptoms and pathology, was described. Subsequently antitoxin therapy and highly effective immunization with toxoid were developed. About 1950, however, it was found that only lysogenic diphtheria bacilli are toxigenic, and therefore pathogenic (Chap. Seven), and it became clear that the etiological agent of diphtheria is, in fact, not a single microorganism but a combination of the bacillus and the appropriate bacterial virus.

It is not yet clear how common the phenomenon of true multiple etiology may be. There are a number of indications that the etiology of many of the infectious diseases

may not be as firmly established as has been thought. For example, there seems to be little doubt of the pathogenicity of the hemolytic streptococci, and yet inoculation of human volunteers with freshly isolated cultures has often given negative results. Similarly, meningococcus meningitis was an important problem in military personnel during World War I but failed to materialize

to a significant degree during World War II in spite of high rates of carriage of the microorganisms. The occurrence of infectious disease is a highly complex phenomenon, involving more than the nature and properties of the causative microorganism, but it is possible that observed discrepancies may be due in part to an oversimplification of its microbial etiology.¹⁰⁹

Microbial Virulence 117, 121

The term "pathogenicity" has been used above in the generally accepted sense of ability to produce disease. It varies widely, not only from one kind of microorganism to another, but also between strains of a single kind of microorganism. A number of other terms denoting disease-producing ability are used, the most common of which is virulence. Here the terms "pathogenicity" and "virulence" are used in the sense suggested by Miles,78 viz., pathogenicity is taken to mean potential ability to produce disease and is applied to groups or species of microorganisms, while virulence is used in the sense of degree of pathogenicity within the group or species. In this way, it is possible to speak of avirulent, virulent, highly virulent, etc., strains within groups or species of microorganisms that are said to be pathogenic.113

It is self-evident that ability to produce disease on the part of a microorganism is expressed only when the disease is produced. Conversely, the resistance of the host (considered in the following section) is determinable only as a reaction to appropriate exposure to the microorganisms. While, then, the two are fundamentally inseparable, for practical purposes they may be measured by holding one relatively constant and varying the other.

Measurement of virulence. The measurement of virulence, then, consists of testing for ability to infect, with observable consequences, "normal" animals such as a standard strain of mice. The consequence observed is ordinarily an all-or-none phenomenon such as death. On challenge inoculation of experimental animals with graded doses of the microorganism, or substances such as bacterial toxins, it is apparent that virulence (or toxicity, etc.) is inversely re-

lated to the size of the effective dose, *i.e.*, the smaller the dose required to kill, for example, the greater the virulence. This is the basis of measurement of virulence (or toxicity) by determination of the minimum lethal dose, the smallest dose required to kill a standard experimental animal.

If each dose is given to groups of experimental animals, ranging in size from a minimum of four to a practical maximum of 10 to 20, rather than individual animals only, two additional points are apparent. First, the proportion of animals reacting in each group varies from none or practically none in the group of animals receiving the smallest dose, to all or practically all of the animals in the group receiving the largest dose. The notation is usually fractional, the numerator the number of animals reacting and the denominator the number of animals inoculated with that dose, and recorded as 0/6, 1/6, 3/6, and 6/6, for example, for the several amounts of challenge inoculum.

Second, when the groups of animals are sufficiently large and the doses graded appropriately, it is apparent also that the proportion of animals affected per unit increment of dose rises slowly at first, then rapidly, and finally slowly again as the proportion becomes large. If the cumulative deaths or other effects are plotted against the logarithms of the doses, the points tend to fall on an S-shaped curve which represents the integral of the frequency distribution of natural resistance in the experimental animals used. When the cumulative effect is plotted on probability paper, on the scale representing the integral of the normal frequency distribution, against the logarithm of the dose, the points tend to fall on a straight line which may be fitted by inspection or by least squares.

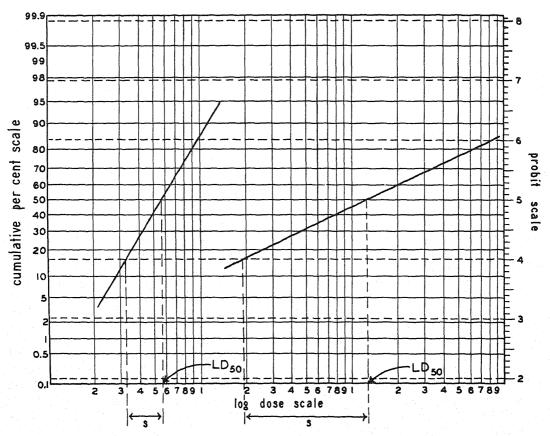

Figure 56. The graphical determination of the interpolated 50 per cent dose (ED_{50}, LD_{50}) and its standard error, s, on probability log paper. The vertical scale is the integral of the normal frequency distribution as per cent cumulative effect, and the horizontal scale is dose. The probit scale is on the right. Steep and less steep dose-response curves are shown.

The ED_{50} . The point on the dose scale at which this line intersects the 50 per cent point in the cumulative effect gives the interpolated dose which would produce the effect in half the animals inoculated with it. This is the 50 per cent effective or ED₅₀ dose, or LD₅₀ dose when death is the response measured. This value is, of course, subject to sampling error, and its precision is indicated by its standard error which is determined graphically also as indicated in the accompanying figure and is written as the $ED_{50} \pm$ the standard error. Such data allow the calculation of the significance of differences between titrations, as, for example, in protection tests (see below).7,8

The standard error is the standard deviation or standard deviate of the normal frequency distribution and is the distance,

in this instance on the dose scale, from center of the distribution to the point of inflection on either side and may, therefore, be either positive or negative to the central point. Since half the deviates are negative, the use of negative numbers may be avoided by adding the number 5; i.e., at the central point the value is 5, at -1 it is 4, at +1 it is 6, and so on. This altered deviate is known as a probit. When the probit values for the cumulative percentage mortalities, or other effects, are plotted against dose on a logarithmic scale the relationship is linear because the probit scale is another way of representing the integral of the normal frequency distribution. The ED₅₀ is the point on the dose scale at which the line fitted by inspection, or more precisely by the least squares method if appropriate, intersects

5 on the probit scale. The probit scale is superimposed on the probability scale in the accompanying figure.

The ED₅₀, or LD₅₀, measure of virulence is subject to qualification in that virulence is also indicated by the slope of the dose response curve. Slopes may vary widely from one pathogenic microorganism to another. When a highly virulent strain of pneumococcus is titrated in the mouse, for example, the dose response curve is steep and usually does not extend beyond a range of two logs on the dose scale. By contrast, when the virulence of Salmonella is titrated in the same animal, the dose response curve is much less steep, extending over as much as six logs on the dose scale. The significance of slope is not clear, but it is obvious that, to continue with the same example, the virulence of pneumococcus and that of Salmonella are not completely comparable as their respective LD₅₀ values alone.

The dose-response curve, or the increasing proportion of deaths as the dose is increased, may be considered to be due to the independent activity of the self-reproducing particles, i.e., to the increasing probability that a single effective microorganism will multiply to a point at which death occurs. Quantitative studies substantiate this in highly susceptible animals, i.e., when the LD₅₀ is very small, but in partially resistant animals for which the LD₅₀ is high, the total number of bacteria at death appears to be a consequence of growth of all the organisms inoculated rather than that of some effective portion.74, 75, 79 The latter is consistent also with the generally observed inverse relation between size of inoculum and length of the incubation period.

Mucin. Many of the microorganisms pathogenic for man are so closely adapted to the human host that they are relatively avirulent for the usual experimental animals. It was first observed by Nungester that the virulence of many such microorganisms, e.g., meningococcus, typhoid bacillus, dysentery bacilli, the cholera vibrio, can be markedly enhanced by inoculation of the bacteria suspended in gastric mucin. The role of mucin appears to be that of protecting the microorganisms against phagocytosis in the usual laboratory titration, but respiratory and alimentary mucus may function to protect the mucosae against infection in naturally occurring infections. Fractionation of this activity of mucins has been of some interest and a series of fractions have been obtained.35 These include a heparin fraction which is also anticomplementary and associated with polysaccharide A, a viscosity fraction which is also a polysaccharide (polysaccharide C) fraction which acts synergistically with the heparin fraction, possibly affecting capillary permeability, and a particulate residue fraction which also acts synergistically with the viscosity fraction, but independently of the heparin fraction. Mucopolysaccharides of other origin, especially bacterial levans, 22, 107 also show some enhancement of virulence, presumably by lodgment in the interstices of capillary endothelium, thus modifying permeability and the inflammatory response.

The enhancement of bacterial virulence by mucin and similar substances, while of very considerable importance in making possible experimental infections otherwise obtainable only with great difficulty, derives its greatest significance from its implications concerning relevant facets of natural resistance.

Infections induced in this way are sufficiently artificial that, when they are used to assay the immune response by either the active or passive method, they give only results open to serious criticism. Obviously the protection demonstrable with such infections by antibody, chemotherapeutic drugs, etc., is a protection of the animal against the effects of mucin as well as against the microorganism.

Protection tests. The virulence titration is often used to assay the efficacy of some treatment such as active or passive immunization, or administration of drugs, by comparing directly or indirectly, the LD₅₀ of a given microorganism for normal animals and that for treated animals. From the analytical point of view, i.e., the design of experiments, more reliable results may be obtained by using a standard challenge inoculum and varying the treatment. In measuring the protective capacity of immune serum by passive immunization of the animals to be inoculated, for example, it is preferable to administer varying amounts of antiserum to groups of animals, followed by challenge with some constant number of microorganisms. Similarly, in the active immunization test for the immunogenic potency of vaccines, groups of animals are given graded

doses of vaccine followed by a constant challenge dose of bacteria after sufficient time to allow the immunity to develop. This preferred procedure is not always possible when the virulence of the challenge microorganism varies widely from one time to another. In such cases the protective material is given in constant dosage, and the LD_{50} dose is titrated in both treated and control animals, and protection measured by the ratio of the LD_{50} in treated animals to that in control animals.

The neutralization test, or serum neutralization test, is a variation on the protection test which is applied to the titration of antitoxin and antibody to viruses. The toxin or infective virus preparation, previously titrated so that the dose is known, is mixed with varied amounts of antiserum, incubated for a time, and the mixture inoculated into susceptible animals. Survival of the animals is indicative of the presence of neutralizing antibody in the serum.

MICROBIAL TOXINS

The derangement of the normal physiological processes that is disease is, in the case of the infectious diseases, a consequence of the toxicity of proliferating microorganisms in the tissues. Toxic substances affecting tissues, cells, and possibly enzyme systems are formed by the microorganisms incidental to their metabolic activities which diffuse more or less freely from the microbial cells, and the cell substance of a wide variety of microorganisms is toxic also. In addition, toxic effects may be produced indirectly, as by the activation of tissue enzymes by bacterial kinases, or the formation of inflammatory and similar toxic substances by the affected tissues, and by the development of hypersensitivity (Chap. Fourteen) to the microbial cell substance.

The toxicities of microbial origin may be separated into three groups, the potent exotoxins, which are the classic bacterial toxins; the endotoxins contained within the intact cell; and a heterogeneous group of toxic substances, often enzymatic in nature, which diffuse more or less freely from the intact cell. Such a separation is artificial, in that lines of demarcation between the groups are often indistinct, but is useful for purposes of discussion.

EXOTOXINS^{51, 69}

The bacterial exotoxins are the most potent poisons known, and it has been calculated that as little as 7 ounces of crystalline botulinum type A toxin would suffice to kill the entire human population of the world. These toxins have their counterparts in the less potent zootoxins such as the snake, spider, and scorpion venoms, and in the phytotoxins such as ricin and abrin. The formation of exotoxins by bacteria is relatively uncommon and is confined to the botulinus bacilli, the diphtheria bacillus, the tetanus bacillus, and one species, Shiga's bacillus, of the dysentery bacilli. The gaseous gangrene bacilli are sometimes regarded as producing exotoxin, but these activities are multiple in that the same strain of bacteria usually produces more than one toxicity, and these activities tend to fall into the group of enzymatically active toxicities.

Crystalline type A botulinum toxin is the most potent of the bacterial toxins; the LD_{50} for the mouse is only 4.5×10^{-9} mg. N. Type B botulinum toxin is somewhat less potent, 5 to 9 \times 10⁻⁹ mg. N/LD₅₀ for the mouse, and crystalline tetanus toxin 6.6 × 10⁻⁷ mg. N/LD₅₀. Highly purified but noncrystalline preparations of diphtheria toxin kill guinea pigs in amounts of $0.4 \mu g$, per kilogram of body weight. The Shiga neurotoxin is of the same order of toxicity in purified form, but relatively small amounts are formed so that crude culture filtrates are not as toxic as those of the botulinus, tetanus, and diphtheria bacilli. While these amounts of toxin are extremely small, the toxins are neurotoxins and are not to be considered as diluted in the entire animal; the lethal dose of botulinum type A toxin for the mouse, for example, is about 20 million molecules, corresponding to about eight molecules per nerve cell.

The potency of these toxins is, in general, paralleled by their efficiency as antigens. Antitoxic serums of high titer, 1 ml. of which will neutralize thousands of guinea pig MLD's may be obtained against diphtheria toxin. The neutralization of exotoxin by antitoxin proceeds according to the law of multiple proportions, i.e., if x units of antitoxin neutralize y units of toxin, nx units of antitoxin will neutralize ny units of toxin.

The exotoxins appear to be proteins; they are denatured by heat, may be salted out of

EXOTOXINS 267

solution etc. The high-molecular-weight botulinum toxins (ca. 1× 10⁶) appear to be polymers and may be broken down into active fragments. Such active fragments of type A and type E toxins have molecular weights of 12,000 to 16,000,^{36, 37} and those of type B toxin a molecular weight of 9000 to 10,000.³⁸ Tetanus and diphtheria toxins have also been prepared in crystalline form, but have not been broken down to smaller active fragments. Diphtheria toxin appears to be a complex, at least antigenically, for multiple antigens are demonstrable by gel diffusion.

With the exception of botulinum toxin, the exotoxins are destroyed by proteolytic enzymes; botulinum toxin is, therefore, the only toxin which is effective when given by mouth.⁶⁰ Dispersion of the polymer by gastrointestinal proteases to more readily absorbable, smaller active fragments may well play a highly significant part in contributing to toxicity by the oral route. There is no chemical evidence which explains, even in part, the toxicity of these substances: these proteins do not seem to differ in any essential respect from bland proteins such as egg albumin. The amino acid composition of crystalline type A botulinum toxin, for example, is in no way unusual. It has been suspected that toxicity might be a property of a prosthetic group attached to the protein molecule, but this appears not to be true; the balance of evidence indicates that the toxicity is a property of the structure of the toxin molecule, possibly of the arrangement of the constituent amino acid molecules in the protein.

The pharmacological action of the soluble toxins resembles that of the vegetable alkaloids and is sometimes quite definite and characteristic for each toxin. Diphtheria toxin, for example, produces degeneration of the heart muscles, kidneys, and liver and the hemorrhagic reaction in the adrenals which is a highly characteristic postmortem finding in the guinea pig.

The nature of the toxicity which results in these changes is not clear, but in this connection the implied nature of the toxin is of considerable interest. Largely through the work of Pappenheimer, considerations of the iron and porphyrin metabolism of diphtheria bacilli in relation to toxin production (Chap. Thirty) strongly suggest that diphtheria toxin may be the protein moiety of

the cytochrome b of the diphtheria bacillus. This raises the interesting possibility that its toxicity may be related to the functioning of the respiratory enzymes of the host cells.

The activity of botulinum toxin has been studied in some detail. It has been found that acetylcholine produces contraction of botulinum-poisoned muscle but not of curare-poisoned muscle. This has been taken to indicate that acetylcholine is not produced in the end plates by the poisoned animal, and the action of the toxin is proximal to the point at which it is produced. Consistent with this, no acetylcholine is released during the neuromuscular paralysis produced by the toxin. The site of action of the toxin is on the nerve filaments, since acetylcholine is released following direct stimulation of the excised diaphragm of the guinea pig, but not following tetanization of the phrenic nerves. The neuromuscular paralysis occurring in the poisoned animal is a result of interference with conduction in the terminal twigs of motor nerves, near or at the points of final branching, but proximal to the site of acetylcholine release. The nature of the activity of the toxin that produces such interference with conduction is, however, completely unknown.

Tetanus toxin appears to act both centrally and peripherally. Its action on the central nervous system appears to be similar to that of strychnine, with suppression of synaptic inhibition. The peripheral effect seems to be two-fold and includes a spastic action at the neuromuscular junction of voluntary muscles (local tetanus) and a paralytic action similar to that of botulinum toxin, *i.e.*, smooth muscles paralyzed by the action of the toxin on their cholinergic nerves still react to acetylcholine.

Following the injection of exotoxins, a period of incubation elapses before symptoms of intoxication appear. This incubation period may be very short or may extend to 36 or 48 hours or longer. The usual incubation period of tetanus toxin is 36 hours, but it may be reduced to 35 to 60 minutes by the injection of very large amounts, 500,000 MLD, of crystalline toxin.

The discovery that the toxic qualities of the soluble toxins are destroyed by treatment with formaldehyde—which, at the same time, leaves the antigenic and antitoxincombining properties of the toxin unimpaired—has been of the greatest practical importance in immunization procedures. Toxin so treated is called toxoid. It might be supposed that this observation would throw some light on the nature of the toxicity of these substances, since formaldehyde is known to block amino groups. Analysis of the formaldehyde-protein derivatives indicates that the aldehyde combines with primary amino and primary amide groups but not with secondary amide or phenolic groups. Because of the effect of formaldehyde on toxicity and the results of detoxification with ketene and phenyl isocyanate, some workers have supposed that the free amino groups of the toxin molecule, such as the ϵ -amino group of lysine, are intimately associated with toxicity.

ENDOTOXINS39, 40, 82, 95, 98

The endotoxins contrast sharply with the exotoxins in that they apparently occur intracellularly in many gram-negative bacteria, especially the enteric bacilli, as lipidpolysaccharide-polypeptide complexes. They are heat-stable, i.e., to boiling, in neutral solution but destroyed by mild acid hydrolysis; are not digested by proteolytic enzymes; are of relatively low toxicity, with the mouse LD₅₀ little less than 0.1 mg.; are only partially neutralized by antiserum; and have substantially the same activity regardless of their origin. They appear to be structural components of the bacterial cell, represent the O antigen and occur, for the most part at least, in the cell wall of the bacteria.

The endotoxins may be extracted from the intact bacterial cell with trichloracetic acid or glycols or aqueous ethyl ether³⁴ and are present in solutions of the cell substance prepared by mechanical disruption either before or after digestion with proteolytic enzymes. The complete complex is extracted in trichloracetic acid and in glycol, and in this form the polypeptide portion does not give the usual qualitative tests for protein. This kind of preparation is known as a Boivin, or Boivin-type, antigen since it was first prepared by the trichloracetic acid extraction method devised by Boivin. The bulk of the lipid fraction may be removed by treatment of the complex with hot formamide and is apparently unrelated either to toxicity or antigenicity. On further degradation the toxicity is often lost, and the free polysaccharide differs according to the kind of bacterium from which the endotoxin was prepared and is responsible for its antigenic character.

The nature of the toxicity is not clear, but Goebel and his collaborators showed that the endotoxin complex of the Flexner dysentery bacillus gave a nontoxic polysaccharide and a toxic acidic protein on acid hydrolysis, and on alkaline alcohol hydrolysis broke down to a toxic polysaccharide and a nontoxic protein. The toxic protein could be detoxified with alkaline alcohol, and the toxic polysaccharide by acid hydrolysis, but it was not possible to characterize the toxic element. Subsequently, a method of extraction with 50 per cent phenol, and removal of the phenol by dialysis or extraction with an immiscible solvent, has been widely applied, 134, 135 which yields a lipopolysaccharide representing the endotoxicity. The small amount of contained lipid is distinct from the larger amount, 10 to 15 per cent, of the Boivin type of preparation and is not removed by extraction with appropriate solvents, and it is presumed to be an integral part of the toxicity. Such preparations may be taken to represent the toxic polysaccharides derived from Boivin antigen by various means. 125

On parenteral inoculation, the endotoxins produce a rise in body temperature, and are sometimes known as bacterial pyrogens, but their pharmacological activity is characteristic in the sense that they increase permeability.127 Capillary permeability may be increased with the production of local hemorrhage, and it is of interest that this occurs more readily in tumor tissue than in normal tissue so that if the dose is adjusted properly hemorrhage may be produced in tumor tissue only. The permeability effect is of interest also in that disease produced by many of the enteric bacilli is characterized by diarrhea. Following intracardial inoculation, grossly apparent edema and congestion with microscopic hemorrhages are produced in the small intestine within an hour or so.11 A characteristic inflammatory response is given on intradermal inoculation, commonly of the rabbit, which may be used for titration of the endotoxic activity61 by inoculation of endotoxin alone, or by potentiation with epinephrine.126 The reaction to endotoxin is strikingly similar to the Shwartzman phenomenon (see below), and it is believed by some that this may account for some, or even a major portion, of their toxicity.

ENDOTOXINS 269

The resemblance of severe intoxication to shock is striking, with fall in arterial blood pressure and rise in venous pressure due to pooling of blood in the portal system, and coincident development of leucopenia and thrombocytopenia. It differs from anaphylactic shock in that clotting time does not increase.132 Endotoxin shock may also occur in bacteremias due to gram-negative bacilli. As noted elsewhere (Chap. Seven), these infections have become much more common with wide use of antibiotic therapy, and such shock becomes of considerable significance because it is often very difficult to differentiate from shock due to myocardial infarction.133

A curious consequence of the parenteral inoculation of endotoxin is an increased resistance of the recipient animal to challenge infection with bacteria or viruses. 118 The mechanism of the effect is quite uncertain, but in the case of viral challenge may be related to the mobilization of endogenous interferon (Chap. Four).

Contrary to the usual impression, the endotoxins are excellent antigens and stimulate the formation of agglutinating and precipitating antibody to high titer. The antibody, however, fails to neutralize the toxicity to more than a minor extent; the endotoxins thus resemble in this respect some artificially prepared pharmacologically active azo antigens whose activity is not neutralized by antibody, though they combine with it.

Viral and rickettsial toxins. 18, 19 Toxic substances are associated with a number of viruses and rickettsiae which are endotoxins in the sense that they have not been dissociated from the infectious agent. While the pathological changes produced by these activities include effects on permeability, they are set apart from the bacterial endotoxins in that they are heat-labile and are neutralized specifically and more effectively, possibly in multiple proportions, by antiserum. Nothing is known as yet of their chemical nature.

Influenza virus, in doses of 1500 to 2000 hemagglutinating units, produces similar changes in the mouse on intravenous inoculation, the more toxic strains producing effects on the intestine such as edema and vascular engorgement. On intracerebral inoculation in the mouse, neurological signs are produced with tremor, clonic convulsions changing to tonic convulsions, and

meningo-encephalitic changes in the brain. Intravenous inoculation of mice with Newcastle disease virus produces changes similar to those found with influenza virus, e.g., lung consolidation and hemorrhagic enteritis.

Microorganisms of the psittacosis-lymphogranuloma group contain a labile toxicity demonstrable by intravenous inoculation of mice, but large doses, equivalent to 40 million infective doses, are required to kill. Mice dying early, *i.e.*, within 12 hours, show lung congestion with scattered hemorrhages, edema fluid in the alveoli, fibrin thrombi in the glomerular capillaries in the kidneys, and foci of damage or necrosis in the liver. In animals dying later, liver damage is the most pronounced feature with numerous necrotic foci accompanied by hemorrhage.

Of the rickettsiae, those causing the typhus fevers and scrub typhus, and possibly also spotted fever, form similar toxins. In the mouse and rat, engorgement of visceral blood vessels and hemorrhagic enteritis with accompanying edema are common features of the acute intoxication. More detailed studies have shown that, shortly after inoculation, vasoconstriction with leakage of plasma and altered capillary permeability occur in the mouse. ¹³¹ In addition, the toxin of the rickettsiae, of endemic typhus at least, produces extensive intravascular hemolysis in the rabbit. ⁸⁶

It is not clear to what extent viral and rickettsial toxins may contribute to the disease process. For example, in one cycle of influenza virus development, 40 to 60 infective particles are liberated from the infected allantoic cell. In volume these represent only a minute portion of the total volume of the cell, perhaps 1.5×10^{-5} , and yet it is sufficient to cause death. The implication would seem to be that replication involves some vital portion of the cell, for the postulated toxicity of the virus to produce death is improbably high. On the other hand, accumulated toxicity may well be a contributing factor in, for example, altering capillary permeability.

OTHER TOXIC SUBSTANCES

In addition to exotoxins and endotoxins, a variety of other substances are formed by microorganisms which may contribute to the disease process, either directly or by facilitating the establishment of a focus of

infection. Some of these are cytotoxic, affecting the red and white blood cells, others interfere, directly or indirectly, with the clotting mechanism, and still others are enzymes catalyzing the decomposition of structural elements of the tissues such as the hyaluronic acid ground substance and collagen. The more important of these activities may be considered briefly.

Hemolysins. A variety of bacteria produce hemolysins, substances which bring about the dissolution of the red blood cells of higher animals. The bacterial hemolysins, which are to be distinguished from the immune hemolysins formed by an animal in response to the injection of red cells of another species, are of two types, the so-called filterable hemolysins, which are extracellular and may be separated from the bacterial cells by filtration, and the hemolysins, which are demonstrated by the cultivation of bacteria on semisolid mediums containing whole blood.

Filterable hemolysins. The filterable hemolysins are sometimes named after the bacteria which form them; a streptolysin, for example, is a hemolysin produced by streptococci, and a staphylolysin a hemolysin of staphylococci. Hemolytic activity is demonstrated by the addition of filtrate or whole culture to a suspension of washed erythrocytes in physiological salt solution; after a period of incubation the red cells are laked, and hemoglobin appears free in solution. The relation of these hemolysins to other naturally occurring hemolysins such as saponins, the hemolysins present in snake venoms, and the like, is uncertain.90 The bacterial hemolysins appear to be protein in nature, are inactivated by heating (55° C. for 30 minutes), and are antigenic; i.e., when injected into animals they stimulate the formation of antihemolysins.

That hemolytic activity is a property of a group of substances of bacterial origin rather than of a single substance formed by a number of bacterial species is indicated not only by differences in immunological specificity but also by the varied properties of the activity. Many hemolysins, for example, are oxygen-stable, but some, produced by the pneumococcus, certain strains of streptococci, and some of the sporulating anaerobes, are oxygen-sensitive; i.e., they are active in the reduced form but inactive in

the oxidized form, the oxidation-reduction being reversible at low temperatures. Hemolysins further differ from one another in their heat and acid resistance and in the incubation time which precedes visible laking of the red cells. Differences in their activity on the erythrocytes of various species of higher animals may be marked; a given hemolysin, for instance, may lyse sheep cells but not rabbit cells. In general, the cells of the animal species from which a bacterium is isolated are more sensitive to its hemolysins than are the cells of other animal species.

A single bacterial strain may form more than one hemolysin. Certain strains of staphylococci form at least two hemolysins, one acting on both rabbit and sheep cells and bringing about a rapid lysis at 37° C., and the other acting only on sheep cells, which are lysed after holding at room temperature overnight—a phenomenon which has been termed "hot-cold" lysis. The former is termed α lysin and the latter β lysin. The action of both can be shown in culture on sheep blood agar, the α lysin producing a zone of complete clearing on 24 hours' incubation and the β lysin producing a zone of darkening which becomes lighter and

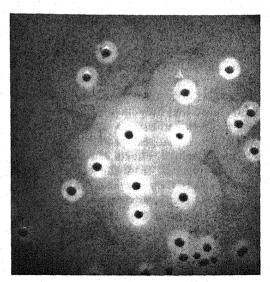

Figure 57. "Hot-cold" hemolysis by Staphylococcus aureus on sheep blood agar, produced by holding the plate alternately at incubator and refrigerator temperatures. The small clear zones are produced in the incubator by the α lysin and the large zones in the refrigerator by the β lysin.

HEMOLYSINS 271

clear on subsequent refrigeration of the plate. Staphylococci produce still other hemolysins in addition to these (Chap. Fifteen).

The occurrence of multiple hemolysins and hot-cold lysins is by no means limited to the staphylococci. Many streptococci, for example, produce two hemolysins, an oxygen-labile heat-stable hemolysin called streptolysin O and an acid-sensitive heat-labile streptolysin S. The occurrence of multiple hemolysins is especially marked among the sporulating obligate anaerobes making up the gas gangrene group. For instance, the most frequently occurring of these, Clostridium welchii, produces three toxins, the α , θ , and κ toxins, of which the first two are hemolysins; and the α toxin is a hot-cold lysin and a lecithinase.

The production of hemolysins is sometimes favored by inclusion of serum in the broth in which the microorganisms are cultured, and it is of some interest that the activity of the hemolysin formed in such mediums is most marked on the red cells of the animal species from which the serum was derived. The hemolytic activity of a culture may be transitory, probably because of inactivation of formed hemolysin. Some hemolysins lose their activity when incubated at 37° C. for two hours or more.

The precise manner in which the structure of the erythrocyte is altered so that contained hemoglobin is released is not clear, but it is an all-or-none phenomenon in that a single cell is not partially lysed. Like certain other hemolytic agents, the bacterial hemolysins apparently alter the surface of the cells, and swelling occurs prior to lysis. The staphylococcal α -hemolysin and streptolysin S have been found to lyse bacterial protoplasts as well as red cells.

Blood-plate hemolysis. The colonies of some bacterial species on blood agar produce visible changes in the medium immediately surrounding the colony which are termed "hemolysis." Two general types of change are observed, one designated as α or green hemolysis, in which the bacterial colony is surrounded by a zone of greenish discoloration, and the other, β hemolysis, in which the zone around the colony is clear and uncolored, in contrast with the red opacity of the medium. Microscopic ex-

amination of the green zone shows the presence of many discolored corpuscles, but in β -hemolytic zones corpuscles cannot be found

The relation between blood-plate hemolysis and the filterable hemolysins is usually regarded as uncertain, for microorganisms hemolytic on blood plates may not appear to produce filterable hemolysin; some workers maintain that, since filterable hemolysins are difficult to demonstrate, failure to find them is not significant. It would appear that the processes involved are different: in the case of the filterable hemolysins the permeability of the red cell is altered and the hemoglobin escapes into the surrounding fluid, while in blood-plate hemolysis the pigment is broken down to green or colorless compounds. In the case of the cholera vibrio the two processes have been sharply differentiated, since the identification of this organism is dependent in part on the hemolysis of goat erythrocytes in suspension (Greig test); though the true cholera vibrio is negative to this test, some strains show hemolysis, or hemodigestion, on blood agar plates (Chap. Twenty-three). On the other hand, there appears to be a close association between β hemolysis and streptoly-

The mechanism of β hemolysis is not well known, but in the case of staphylococcal hemolysins, the hemoglobin is not destroyed; according to Christie and Graydon the clearing around the colony is due to migration of the liberated hemoglobin. Green hemolysis was formerly thought to be due to the formation of methemoglobin and associated with the formation of hydrogen peroxide, but it has been found that the green substance is an iron-containing derivative of hemoglobin possibly formed by reduction. As in the case of the filterable hemolysins, hemolysis on blood agar is frequently species-specific; a higher proportion of bacterial strains will show hemolysis on blood from one animal species and not on that of another.

The relation of ability to form hemolysin and virulence is obscure. Although among some of the parasitic bacteria such as streptococci and staphylococci virulence is associated with hemolytic activity, a number of saprophytic bacteria also produce hemolysins. On the other hand, it has been

reported that in staphylococcus infections of the udder, the hemolytic strains are much more irritating than the nonhemolytic organisms. It might be expected that infection with actively hemolytic bacteria would be accompanied by anemia and hemoglobinuria, but this is not the case as a rule; infections with Cl. welchii, however, are frequently characterized by gross blood destruction and consequent severe anemia and jaundice which is due to the continuous release of the hemolytic α toxin. The massive intravascular hemolysis and associated hemoglobinuria, together with hyperkalemia, produced by the toxin of scrub typhus rickettsiae referred to above, may be a significant part of the pathological picture of this disease. In many instances, of course, a bacterial hemolysin may be toxic in other ways; i.e., bacterial toxins are sometimes hemolytic.

Leucocidins. A number of bacteria, nostaphylococci, streptococci. tably pneumococci, form leucocidins, substances which kill and, in some cases, lyse, polymorphonuclear leucocytes. The death of the leucocytes results in the inability of these cells to reduce methylene blue, a phenomenon made use of to demonstrate the activity of these substances.72 A direct microscopic method using phase contrast microscopy has shed some light on the effect of these substances on the white blood cell. The leucocidin so demonstrable is the socalled Panton-Valentine (PV) leucocidin; this leucocidin is a two component system in which the two factors, separable by ion exchange chromatography, function synergistically. Human and rabbit leucocytes in contact with leucocidin become spherical; the nuclei fragment and the cells may, with some leucocidins, eventually burst or, with others, remain intact.

The amount of leucocidin produced by one bacterial species may vary widely from one strain to another, and a single strain may produce more than one leucocidin. The detection of more than one leucocidin is dependent upon differences in thermostability and in the kind of leucocytes attacked; one staphylococcal leucocidin, for example, affects both rabbit and human leucocytes, while another is active only on rabbit cells. In general, the leucocidins closely resemble the filterable hemolysins in that they are antigenic, variable in their heat resistance,

and so on, and, in some cases, may be identical with hemolysins. The α hemolysin of staphylococcus, for example, is a leucocidin and is known as the Neisser-Wechsberg leucocidin. They may not be strain-specific; some of the staphylococcal leucocidins, for example, are immunologically similar if not identical regardless of the bacterial strain from which they are derived.

The part played by the leucocidins in the virulence of a bacterium is obscure. Theoretically, it should be of some advantage to an invading microorganism to be able to destroy these phagocytic cells and thereby break down, to some degree, the defenses of the body. The polymorphonuclear leucocytes are not, however, the most important cells in the phagocytic destruction of bacteria, and the effect of these substances on the other phagocytic cells, the mononuclears, the histiocytes, and others, is not well known. As in the case of the hemolysins, the leucocidins of bacterial origin must be differentiated from the immune leucocidins, those produced by the animal body in response to the injection of leucocytes from another species.

Coagulase. The formation of blood clots is accelerated by coagulase, a substance of bacterial origin. The production of coagulase is apparently confined to the staphylococci for the most part and may be causally related to thrombus formation that is common in infections with these organisms. Occasional strains of other bacteria such as Pseudomonas aeruginosa, Serratia marcescens, Escherichia coli, and Bacillus subtilis have also been observed to accelerate the clotting of blood. Coagulase activity is demonstrated by the addition of bacteria to citrated or oxalated blood plasma (human or rabbit), which gels within three hours. It is also demonstrable by mixing the bacteria with plasma on a slide and examining for the clumping that occurs with fibrin formation—the plasma-clumping test.

It has been found that the formation of a clot occurs in two stages, viz., a reaction between the substance produced by the bacteria, procoagulase, with a cofactor or activator present in plasma to form the clotting agent, coagulase, and clotting of the plasma under the influence of coagulase. While, then, strictly speaking, the bacterial factor is procoagulase, it is commonly referred to as coagulase. It is relatively heat-

stable and may be obtained cell-free with some difficulty. It is antigenic, although with some complications, and occurs as a number of antigenic types, more than one of which may be produced by a single strain of staphylococcus. The plasma factor is closely similar to, but not identical with, prothrombin from which it may be separated by Seitz filtration (prothrombin is retained) and is associated with the globulin fraction. There is some evidence that coagulase occurs in two forms, one bound to the cell and the other free; one bound to the cell and the other free; the former is presumably involved in the plasma-clumping test.

The distribution of the plasma factor among animal species accounts for the differences in the clotting behavior of plasma; most coagulases clot human, rabbit, and horse plasma, but not rat, chicken, or guinea pig plasma, though the last may clot slowly at 25° C. but not at 37° C. It is generally agreed that the formation of coagulase by staphylococci is closely associated with virulence, and reference is commonly made "coagulase-positive to staphylococci," implying virulent staphylococci. There is an association between the susceptibility of animals to staphylococcal infection and formation of the plasma cofactor. Thus rats, mice, and guinea pigs are usually relatively resistant to experimental infection with coagulase-positive staphylococci, and the virulence of coagulase-positive staphylococci for such animals can be enhanced by inoculating with bacteria suspended in coagulable plasma. Apparently bacteria coated with a film of fibrin are phagocytosed with difficulty, and, in addition, the clumping of both bacteria and phagocytic cells by fibrin tends to inhibit mechanically the process of phagocytosis. Further, it has been observed that coagulase antagonizes, to a greater or lesser extent, the antibacterial activity of normal serum, and coagulasepositive bacteria are able to grow in normal serum while coagulase-negative are not.28

The bacterial kinases. A number of kinds of bacteria, notably the streptococci, are able to dissolve fibrin clots or inhibit the clotting of plasma. This activity was described by Tillett and Garner in 1933 as fibrinolysin. It may be titrated as the highest dilution that will lyse a fibrin clot in a given time, or as the time required to lyse a fibrin clot, or, finally, by the amount of

protein made soluble in trichloracetic acid. The last is the least sensitive because dissolution of the clot occurs earlier than proteolysis to trichloracetic acid—soluble substances or free amino nitrogen.

The reaction does not occur with a clot formed by the interaction of purified human thrombin and fibrinogen. It has been shown that the factor produced by streptococci is not in itself the lytic substance, but a kinase that activates a precursor (plasminogen) of a plasma protease (plasmin) occurring in the euglobulin, and that the plasmin is actually the lytic agent. The bacteria activity, then, is not a fibrinolysin as it was originally and still is called, and is more properly referred to as a kinase, streptokinase in the case of the streptococcal activity.

Streptokinase. There are certain anomalies in the bacterial activity. For example, streptococci of human origin will lyse human plasma clots, but the plasma of most animals is not susceptible. Animal fibrin is, however, susceptible if clotted with human thrombin, and human fibrin is susceptible if clotted with animal thrombin. Moreover, rabbit clots become susceptible if mixed with plasminogen of human origin. Such observations are in large part explained by the occurrence of both free plasmin and a plasmin inhibitor, antiplasmin, in plasma, the latter in the albumin fraction. Thus the insusceptibility of rabbit plasma is due to the presence of relatively large amounts of antiplasmin rather than a deficiency in plasminogen as once thought. Similarly, on dilution of plasma, the plasmin-antiplasmin complex dissociates, and the solution becomes fibrinolytic. Inactivation of antiplasmin by chloroform has been utilized as the basis of a commercial purification of antiserum; the antiserum is shaken with chloroform and incubated to allow the preferential digestion of serum proteins other than antibody globulin to occur.

Fibrinolytic, or lysokinase, activity occurs among bacteria other than the streptococci. That of staphylococci, staphylokinase, is somewhat different from the streptokinases in species specificity and other respects; there is some evidence that staphylococci that produce β lysin (hemolysin) do not produce staphylokinase. A variety of other bacteria, including enteric bacilli and some of the sporulating obligate anaerobes, digest fibrin clots, but for the most part not a great

deal is known about these activities and possibly in some instances the digestion is due to proteolytic enzymes rather than kinases.

The streptokinases are antigenic and those from different strains appear to be very similar immunologically. Antiserums specifically inhibit the activity, and the occurrence of antikinase in the serum has been useful as an indicator of past infection with kinase-positive streptococci.

A number of bacteria exhibit a tendency to inhibit the clotting of plasma, a property that may be demonstrated by delaying the addition of calcium to the oxalated plasma; when calcium is added after a period of preliminary incubation, the clot fails to form. This property has been most often demonstrated with cultures in dextrose broth, and, in some cases at least, the failure of the plasma to clot is a result of the presence of lactic and other acids formed in the fermentation.

Streptokinase appears to be closely associated with virulence and particularly with the ability to invade the body tissues. Since one of the first reactions of the body to tissue destruction is the formation of blood clots which tend to wall off and isolate the infected region, it is not surprising that a bacterium capable of lysing these clots should show marked tendencies to extensive tissue invasion. The streptococci are among the most invasive of the pathogenic forms, and this phase of their virulence may be attributed in part to the formation of fibrinolysin.

Hyaluronidase (spreading factor, invasin).25,73 The permeability of the tissues is remarkably increased by a factor, often called the Duran-Reynals factor after its discoverer, present in certain mammalian tissues, notably the testes. Bacteria, vaccinia virus, and substances such as toxins, India ink, and the like, diffuse rapidly from the site of inoculation when injected in conjunction with extracts containing this factor. Strains of staphylococci and streptococci that have no pronounced invasive powers may, in this way, be rendered highly invasive, and hyaluronidase is apparently essential for producing inhalation infection.^{21, 55} This factor is also present in a number of bacteria notable for their invasive properties, such as certain strains of staphylococci and streptococci, pneumococci, and certain of the obligate anaerobes such as the bacillus of gas gangrene. Among some of these organisms there is some degree of association between content of the Duran-Reynals factor and virulence; the noninvasive strains of staphylococci noted above contain little or none of this factor, but become invasive when it is supplied, while the invasive strains produce the factor themselves.

This substance is an enzyme, hyaluronidase, whose substrate is hyaluronic acid, a mucopolysaccharide consisting of acetylglucosamine and glucuronic acid, which acts as a cement substance of the tissues and is found in synovial fluid and elsewhere in the body.

Decomposition of hyaluronic acid occurs in three stages, viz., in the first it is no longer precipitable with acetic acid, the second stage is that of depolymerization and coincident decrease in viscosity, and the third is characterized by the liberation of reducing sugars. Each of these has been used for assay of hyaluronidase activity, and most in vitro methods are based on viscosity changes. The action of the enzyme in decreasing the viscosity of hyaluronic acid by hydrolysis is responsible for facilitating the penetration of the tissues by bacteria that produce it. The effect on the tissues is temporary in that, following inoculation of preparations of the enzyme, the dermal barrier is restored partially in 24 hours and completely in 48 hours.

It is of some interest that hyaluronic acid is also found in the capsular substance of some strains of streptococci. Such strains do not produce hyaluronidase and in its presence are denuded of capsules and more readily phagocytosed (see below). The ability of such strains to invade the tissues does not, of course, depend upon their elaboration of hyaluronidase. The activity appears to be antigenic, in that it is neutralized by antiserums, but immunologically distinct from different sources; it has been suggested that the enzyme is combined with different proteins in different organisms.

Hyaluronidase is antagonized by an enzyme present in normal blood plasma which has been called anti-invasin I. An enzyme in bacteria, pro-invasin I, destroys anti-invasin I, and another enzyme in plasma, anti-invasin II, destroys pro-invasin I. It has been suggested that a balance between

CAPSULES 275

all these in the host-bacterial system determines whether or not invasion of the tissues will occur.

Streptodornase. Streptodornase is a deoxyribonuclease produced by many hemolytic streptococci, together with streptokinase, which depolymerizes viscous DNA, and its activity may be titrated by viscosity methods. It appears to be unrelated to virulence. Both streptodornase and streptokinase are available for the enzymatic debridement of wounds. The functioning of the latter depends upon the presence of sufficient plasminogen. Plasminogen is not available generally for this purpose, but may be prepared from human plasma.¹⁷

CAPSULES

The association between the presence of a capsule on a pathogenic bacterium and its virulence has been discussed elsewhere (Chaps. Three and Seven). The capsular material, generally polysaccharide in nature although nitrogen and amino acids may be present, is not in itself toxic and cannot be regarded as analogous to toxins, hemolysins, and similar substances. Rather the capsule appears to function as a defensive mechanism of the bacterium against the phagocytic activity of the leucocytes. Encapsulated bacteria may be ingested by a white blood cell but, instead of being killed and digested. remain within the phagocyte for a time and then may be extruded in a viable condition. The ability of an encapsulated bacterium to resist phagocytic destruction may, in fact, result in a wider distribution of the microorganism than it might otherwise attain, through transport within the phagocytic cell. It is of some interest in this connection that nonencapsulated, avirulent pneumococci are highly virulent for rabbits deprived of their leucocytes. It is perhaps suggestive that the polypeptide material making up the capsule of the anthrax bacillus contains D(-) glutamic acid. Since proteolytic enzymes attack only polypeptides built up from amino acids of the L-series, possibly an encapsulated anthrax bacillus would be highly resistant to the digestive enzymes of a phagocytic cell.

Whether the association of virulence and capsule formation may be entirely accounted for on the basis of bacterial defense against

phagocytic destruction is not entirely certain, but such defense undoubtedly plays an important part. The presence of antibodies to the capsular substance breaks down this bacterial resistance, and immunization to the capsular material of the pneumococcus, for example, produces just as high a degree of immunity to pneumococcal infection as immunization to the entire bacterium.

MISCELLANEOUS FACTORS

In addition to these more or less well defined and better known factors, a number of bacteria have been reported to produce substances which may be associated with virulence. Such, for example, are the necrotizing factor, or necrotoxin, produced by some staphylococci, which kills tissue cells; a hypothermic factor produced by Shiga dysentery bacilli, which lowers body temperature; an edema-producing substance formed by pneumococci; substances associated with the endotoxins of some of the enteric bacteria which affect the blood sugar levels of animals. Unfortunately, the discontinuous character of present information does not support any satisfactory generalization regarding bacterial virulence, but it seems clear that a pathogenic bacterium may have at its disposal a series of mechanisms, in combination peculiar to itself, which make possible a successful invasion of the tissues of the host.

TOXICITY OF HOST ORIGIN

It is not uncommon to observe signs of toxemia in infectious disease when the causative microorganism cannot be shown to form toxic substances in vitro. The classic example of this is the marked toxemia of acute pneumococcal infection, while the pneumococcus cell substance and metabolic products formed in culture are comparatively bland. Observations of this kind suggest either that toxicity is of host origin, in that it is produced by the infected host tissue, or that the microorganism produces toxic substances in the environment of the infected tissue but not in culture in vitro.

There are two obvious alternatives in the former. It may be postulated that, in the interaction of the metabolic systems of the proliferating microorganism and the host cells, those of the latter are perverted with the accumulation of substances toxic to the host. While there is no definitive evidence of such interaction, the plausibility of the hypothesis is enhanced by the relatively rapid disappearance of signs of toxemia on institution of chemotherapy. The chemotherapeutic drugs are not antitoxic, though some small effects on microbial toxins have been described, but they inhibit proliferation of the microorganism, suggesting that the active metabolism of the growing microorganism may be associated with toxicity. Perhaps similarly, in gaseous gangrene (Chap. Twenty-nine) the host is in shock although systemic toxin is not detectable, and antitoxin is ineffective; amputation of the affected limb relieves general symptoms.

The other alternative is a more or less specific interference by a bacterial product with a functional system of the host. Two examples of this have been described above. One is the activation of plasminogen by the antagonism of the bacterial kinases, such as streptokinase, for its normal inhibitor, antiplasmin. The other is the staphyloinaccurately product, coagulase, which activates a plasma cofactor separable from prothrombin. In some instances it may be shown that toxic substances are produced by the host tissue. The thromboplastic toxin, or necrosin, that may be isolated from skin lesions of streptococcal etiology may also be found in normal skin subjected to traumatic iniurv. 20, 103

Other phenomena of this kind are less well understood. There is, for example, good evidence that the febrile response to bacterial substance often is not due to pyrogenic substances present in the microorganism but is a consequence of an interaction between the bacterial substance and plasma to form, or liberate, pyrogenic substances of endogenous origin.43 Still another such phenomenon is the greatly increased sensitivity to histamine, on the order of a hundred-fold, that is developed following inoculation with pertussis bacilli and that is perhaps attributable to an effect on the rate of histamine release from the tissues. This kind of "hypersensitivity" is possibly related to the pathogenesis of whooping cough in which the "whoop" persists after

the bacteria can no longer be found in the infected individual. In this connection it is suggestive that the sensitivity to histamine so produced is more marked in female than in male mice, and in whooping cough the general rule that mortality from infectious disease is significantly greater in the male is reversed.

The Shwartzman phenomenon. 108, 128 The reaction known as the Shwartzman phenomenon may be regarded as a special case of a host reaction resulting in increased sensitivity to microbial substances. It occurs most readily in the rabbit and is produced by two inoculations, a "preparatory" inoculation and a "provocative" inoculation, a few (8 to 30) hours apart, and the reaction so produced may be local or general. In the former, the preparatory inoculation is given intradermally, and the provocative inoculation intravenously; a short time after the second inoculation gross hemorrhage and necrosis develop at the site of the preparatory inoculation. The general reaction is induced by giving both inoculations intravenously and is characterized by bilateral cortical necrosis of the kidneys. While the time element and the lack of necessity for a common antigenicity in the preand provocative substances paratory precludes an immunological basis for the reaction, it resembles overtly the Arthus phenomenon (Chap. Fourteen) and is intensified when the animal has received immunizing inoculations of the preparatory material.

Not all bacteria contain preparatory substances, but the endotoxins of the enteric bacilli are almost uniformly effective. It has, in fact, been suggested, especially by Stetson, that the toxicity of many bacterial endotoxins may be a manifestation of the Shwartzman reaction, possibly enhanced by an immune response in some instances, in which the preparatory dose is absorbed from the bowel as endotoxin of coliform and related components of the normal intestinal flora. There is a wider range of provocative than of preparatory substances, and substances such as starch or agar, serum, or bacteria which have no preparatory effect may be provocative.

The participation of the host in this reaction is indicated in a number of ways. Following the preparatory intradermal inoculation, there is a local cellular reac-

RESISTANCE 277

tion around the venules in the area, an increased glycolysis associated with the influx of heterophils, and a local accumulation of lactic acid. This response, and subsequent reaction to the provocative inoculation, is prevented by treatment which induces leucopenia, such as x-irradiation or the administration of nitrogen mustards. The significance of the cellular response is also indicated by the enhancement of the reaction when the macrophage system is blockaded with Thorotrast and an increased sensitivity to endotoxin preparatory inoculation when the animal is treated with cortisone. In total, the evidence suggests the preparatory inoculation interferes with a significant detoxifying mechanism.

Local infection with a variety of bacteria, such as tubercle, anthrax, and influenza bacilli and streptococci, are preparatory even though the microorganism itself may not be preparatory. Thus streptococci are not preparatory though a local streptococcal infection may be, and preparatory activity may be demonstrated in extracts of the infected tissue. The extent to which the Shwartzman type of reaction contributes to the pathogenesis of infectious diseases is, however, not at all clear.

Microbial toxins formed in tissues. The second possibility alluded to above is that of the production of toxin by the microorganism only in the environment provided by the infected tissue. This is suggested by, for example, the increased virulence that may be induced by animal passage, the inability to differentiate *in vitro* between virulent and avirulent strains of certain microorganisms such as the plague bacillus, and by the contrast between anthrax bacilli *in vitro* and *in vivo*.

The last is one of the most thoroughly studied instances of this kind. It is considered in more detail elsewhere (Chap. Twenty-eight) but may be noted briefly here for illustrative purposes. There is little or no evidence of toxicity of the usual in vitro culture of the anthrax bacillus, nor can effective killed vaccines be prepared from such cultures even though the bacilli may be shown, by animal inoculation, to be highly virulent and to produce an immunizing infection. While a number of factors are involved, it suffices for present purposes to note that an effective immunizing antigen may be extracted from infected tissue, and elucidation of the nutritive requirements for its production have allowed the development of culture mediums in which it is formed in vitro. This immunizing substance is not of sufficient toxicity to account for the death of infected animals. but such toxicity is demonstrable in the plasma of infected animals. This toxicity is separable into two fractions, one of which is sedimented by high speed centrifugation while the other is not. Separately the two are only moderately toxic, but when combined their toxicity is synergistic. The sedimentable fraction resembles the immunizing antigen, differing in that it is toxic when combined with the nonsedimentable fraction, and the immunizing antigen may be a "toxoided" form of the toxic fraction. It is not yet known in what way the tissue environment makes possible the formation of these toxic substances, but it is clear that the toxigenicity of these bacteria, and no doubt others also, in the infected animal is not adequately reflected in the toxic activities of in vitro cultures.

Resistance 106, 122

It is already apparent from the foregoing considerations of microbial virulence that, although the ability of a microorganism to produce disease is conditioned by a series of mechanisms originating with the microorganism, pathogenicity must be evaluated in terms of the resistance of the host. As a rule, a pathogenic microorganism is limited to a small number of hosts; microorganisms pathogenic for animals are not ordinarily

pathogenic for plants; very few of the microorganisms that can infect mammals are also pathogenic for cold-blooded animals; some are even restricted to the tissues of a single species. Resistance, like virulence, is made up of many factors, some of which are known either in more or less specific form or in the terms of generalities that serve as a cloak for ignorance; others are, in all probability, as yet unsuspected.

Resistance to infection is, in a sense, somewhat more complex than virulence for, as will appear, not only are there specific barriers to infection variable with respect to species and even from one tissue to another in the body of a single animal, but the efficiency of these barriers is also a manifestation of general physiological well-being, and hence they are subject to extrinsic or environmental stress.

The factors operable in the host are of two general kinds, the constitutive group, which includes those which occur in the normal animal, and the adaptive group which are the responses to the presence of the pathogenic microorganism. The latter are predominantly, though not entirely, those associated with the immune response, and are considered elsewhere (Chaps. Thirteen and Fourteen), while the former are discussed here.

Species. racial, and inherited resistance. $^{41, 123}$ Species of higher organisms differ greatly from one another in their resistance to any given disease, a fact that has been suggested earlier in connection with the experimental reproduction of disease. In many cases resistance to infection is relative, for disease may sometimes be produced by the administration of massive doses of bacteria to a resistant animal, but in others it appears to be absolute. Man is. for example, apparently completely immune to cattle plague, and many of the lower animals are equally resistant to some diseases of man. In general the factors underlying differences in species resistance are unknown, but in a few cases body temperature or differences in anatomical structure have been found to account for the observed variation. Pasteur's classic experiment in which he rendered the naturally resistant hen susceptible to anthrax by chilling it in cold water, and the converse of this experiment, the production of anthrax in the resistant frog by raising its body temperature from 25° to 35° C., may be explained in terms of unfavorable body temperatures. Similarly, cold-blooded animals are not susceptible to human tuberculosis, and warm-blooded animals are not infected by the tubercle bacilli of cold-blooded animals. 99 The insusceptibility of experimental animals such as guinea pigs and rabbits to the enterotoxin produced by some bacteria is possibly attributable to their lack of a vomiting mechanism. As indicated earlier, resistance to a given infectious agent is not necessarily associated with phylogenetic relationships, and there is no pattern from which the resistance or susceptibility of an animal can be predicted by logical processes; the tabulation of animals that are susceptible to a given disease represents information that has been acquired largely by trial and error.

Domestic and experimental animals. Not only do species of higher organisms differ in their resistance to infectious disease but the races comprising a susceptible species likewise appear to differ among themselves. There are many instances of differences in resistance to infectious disease in varieties or strains of animals. The relative resistance of Algerian sheep to anthrax is well known, and inbred Berkshire swine have been found to be highly resistant to brucellosis. That this is true racial immunity which is, as might be expected, inheritable has been demonstrated by extensive experimental investigations with laboratory animals. The earlier studies of Wright and Lewis showed that marked differences in susceptibility to tuberculosis existed between inbred families of guinea pigs, differences which were transmitted to the offspring. In subsequent work⁴² it has been shown that resistance to infection may be raised or lowered by selective breeding, sometimes to a remarkable degree. Lurie has bred strains of rabbits resistant and susceptible to infection with tubercle bacilli. When subject to inhalation infection with human tubercle bacilli, the response of the animal is essentially all or none and sharply illustrates the role of genetic factors; in the resistant animal the bacilli multiply for only a short time and are then destroyed, while in the susceptible animal they proliferate freely for long periods. 66 The resistance of mice to infection with tubercle bacilli seems also to be affected by genetic constitution.68

It is of interest that resistance to bacterial endotoxin may also be raised or lowered by selective breeding. Resistance does not behave as a simple Mendelian character but is to some extent specific in that a race having increased resistance to infection with one microorganism is not necessarily unusually resistant to another. For example, in Webster's work mice selected for resistance to infection with Salmonella enteritidis

showed increased resistance to pneumococcus and Friedländer's bacillus infection but were more susceptible to the virus of louping ill than the strain selected for susceptibility. In a general way, it appears that inherited resistance is, to a degree, specific in that it is effective against groups of related infections rather than against infection in general.

Considerable interest has attached to the mechanisms underlying inherited resistance and susceptibility. Thus, in Lurie's studies resistance was associated with low skin permeability as assayed by intradermal inoculation of India ink, increased rate and intensity of antibody (agglutinin) response, and the development of a high degree of hypersensitivity. It has been found that in mice there is a marked correlation between numbers of leucocytes and resistance to mouse typhoid, and macrophage function in general appears to be involved.65 Similarly, resistance and susceptibility of breeds of chickens to Sal. pullorum infection are associated with numbers of lymphocytes; differences in liver and spleen in resistant strains of mice are associated with the ability of macrophages to digest phagocytosed bacteria, and strains of chickens genetically resistant to Sal. gallinarum infection have higher body temperatures than susceptible strains, and this was combined with more active phagocytosis. Resistance to virus infections is also determined by genetic factors.1

While such correlations as the foregoing are suggestive, in general it has not been possible to associate resistance with any single character; rather it appears to be dependent upon a complex interaction of characters that, individually, do not account for the observed resistance. The inheritance of resistance to influenza virus, however, is considered to be determined by a single dominant autosomal allele.64 Differences in susceptibility may, of course, be a reflection of corresponding differences in immunizability, i.e., ability to respond to antigenic stimuli with antibody production, as in Lurie's resistant rabbits, and the immune response to toxoids behaves similarly.53

Races of man.¹⁰⁴ The relative resistance of races of man to infection has been the subject of considerable interest and such investigation as has been possible. Under

ordinary circumstances in this country the nonwhite races are much more susceptible to infectious disease than the white race. There are, however, certain exceptions. Thus, the influenza epidemic of 1918 appears to have had a greater impact upon the death rate for white youths than upon that for the nonwhite population in the same age group. A similar exception may be noted in the case of Baltimore Negroes, who showed a lower ratio of clinical diphtheria to immunizing infections than corresponding white children. It is quite generally recognized, too, that the Negro has a remarkable degree of resistance to erysipelas, and the more favorable response of the Negro to all forms of treatment for gonorrhea is well known.

Special interest has attached to the white and nonwhite tuberculosis death rates, both crude and age-specific. Whether the observed high mortality in the nonwhite represents a racial susceptibility or is entirely a reflection of economic status has been the subject of considerable discussion.⁵⁹

There also appear to be differences between the less well-defined "races" of man. There is evidence that the Irish are less resistant to tuberculosis than certain other elements of the American population, such as the Italians. On the other hand, the Jewish race is considered by many to be relatively resistant to tuberculosis; in spite of a high incidence of infection, the mortality is very low. To what degree the evidence supports the hypothesis that races of man differ in their susceptibility to this and other diseases, such as pneumonia, is problematical, for adequate control of the environmental factors is difficult if not impossible.

In general, appropriate data on the hereditary transmission of susceptibility, or resistance, to infection in man are not available, but two kinds of evidence suggest that hereditary factors are involved. The best of such data are twin studies, monozygotic and dizygotic, the latter serving as controls. Many of these have concerned tuberculosis, and most are in agreement that there is a hereditary element in susceptibility,110 and similar studies of susceptibility to poliomyelitis have indicated that susceptibility to the paralytic form of the disease may be conditioned by the heterozygous state of a recessive gene. 50 A hereditary element is suspected when a disease seems to "run in families." Rheumatic fever is such a disease, and the observed associations between incidence of the disease and blood relationship appear to be significant. But, in general, association of infectious disease—incidence or severity—with human blood groups is questionable. The question is one of the occurrence of practically significant genetic segregation.

One of the best established cases of hereditary control of resistance to a specific infection is that of the relative insusceptibility to certain kinds of malarial infection associated with sickle-cell anemia and the anemia, thalassemia.111 Mediterranean These anemias are almost invariably fatal in the homozygous individual, but the individual, heterozygous for the appropriate gene, is considerably more resistant to malarial infection than the individual in whom these genes do not occur. In sicklecell anemia hemoglobin synthesis is affected directly by the gene, and in the abnormal hemoglobin (hemoglobin S) valine is substituted for glutamic acid at one point in the peptide chain. In thalassemia the expression of the genes responsible for hemoglobin synthesis is affected quantitatively to give excessive production of the fetal type of hemoglobin (hemoglobin F). It is probable that the presence of such hemoglobins in the red blood cell makes it less susceptible to infection with malarial parasites.

A given disease, however, may be relatively mild in its effect on races of man that have been in contact with it over a long period, but may assume a highly virulent form in other races to which it is new. Measles, for example, a mild disease to civilized man, has been a scourge to certain primitive races. In other cases, diseases originally highly virulent have become apparently less so with the passage of time; leprosy is not as widespread as it was in Biblical times, and syphilis is a considerably milder disease today than it was in the sixteenth century. Phenomena such as these have been taken by some to indicate the development of a racial immunity through a selection of more resistant individuals, and by others to suggest an adaptation of the microorganism accompanied by a loss of virulence. At the present time, it is not possible to differentiate sharply between these two; possibly both effects are operative.

It should be pointed out in this connection that what might be called a pseudo-racial immunity may be manifested by a race in close association with a given infective agent. Many individuals have the disease. the survivors are immune, and this immunity is passively transferred to the offspring, who are infected before this passive immunity entirely disappears and consequently have the disease in a mild form but become solidly immune. The immunity is passively transferred to the third generation, and the process continues ad infinitum as long as the race is in contact with the disease. Some such mechanism as this appears to account for the apparent racial immunity of the West African Negro to yellow fever; the immunity of adults arises as a result of mild infection in childhood.

Age. 116 In a general way, resistance to infection increases with age, but there are a number of important exceptions. Embryonic and fetal tissues have little resistance, and susceptibility remains high for a variable, but short, time post partum. The chick embryo and associated membranes may be readily infected with a variety of agents, particularly viruses and rickettsiae, to which the chicken, is for all practical purposes, completely resistant. Similarly, on growth on culture in vitro, tissue explants tend to assume the physiological character of embryonic or neoplastic tissue and are susceptible to infection with a variety of agents. The persistence of susceptibility post partum is taken advantage of in the propagation of certain infectious agents, such as certain strains of poliovirus in suckling mice or the enteric infection of the suckling rabbit with the cholera vibrio.

An important factor, though not the only one, in the susceptibility of the very young to infection is the lack of an immune response. This is compensated for in the newborn mammal, so far as survival is concerned, by the presence of antibody of maternal origin (Chap. Fourteen) which serves to provide temporary protection against the diversity of microorganisms encountered on emerging from a sterile environment. Occasionally this may not be sufficient, and fatal systemic infection with microorganisms not usually regarded as pathogenic can occur. Such infections with coliform bacilli are occasionally observed in human infants, and the disease of

stood.

foals known as scours is a septicemia of coliform etiology. Apparently the immune mechanism is poorly developed even at birth, and the extremely young tissue is unable to distinguish the "not self" of foreign proteins and other antigenic substances. This has the practical consequence that prophylactic immunization of the newborn human infant is relatively ineffective.

The predominance of the diseases of childhood is not necessarily due to an unusual lack of nonspecific resistance in the pre-adolescent age groups. Man appears to be highly susceptible to diseases such as measles, mumps, and chickenpox, but the infectious agents are sufficiently prevalent in the human population that the probability of encountering them early in life is great. When the child is relatively isolated, as in certain rural areas, the probability of contracting such a disease is less, and it tends to appear later in life. It is for this reason that the so-called diseases of childhood tend to be a problem when young adults are suddenly aggregated as in military groups; such groups include a fair proportion of individuals who have, by chance, not vet contracted immunizing infections in childhood.

By puberty the average individual has acquired a variety of immunities, with or without overt evidence of infection, which are similar to the pseudo-racial immunity described above. The juxtaposition of such acquired immunities with puberty has led, from time to time, to the postulation of a "maturation immunity," a state of enhanced resistance presumed to be causally related to sexual maturity. Such an explanation for the greater resistance to diphtheria of the young adult was offered many years ago, but it was shown that this is, in fact, the result of immunizing, but inapparent, infections in childhood. Such an explanation of resistance to poliomyelitis on the part of adults was current for a time until it became clear that infection with poliovirus is very common, only the rare individual showing paralytic symptoms. Further, attempts to demonstrate a maturation immunity in experimental animals in which sexual precocity has been induced by the administration of sex hormones have failed to provide supporting evidence. The naturally occurring association between sexual maturation and resistance to infectious disease appears

to be fortuitous and not indicative of a causal relationship.

Other differences in susceptibility to infectious disease associated with age do, however, appear to have a physiological rather than an immunological basis. The two best established examples are those of the occurrence of acute fatal pulmonary tuberculosis in the young adult and the marked susceptibility of the aged to pneumococcus and similar pneumonias.

Infection with the tubercle bacillus (Chap. Thirty-one) is markedly influenced by predisposing factors, a characteristic of a wellestablished balance between host and parasite. In addition to factors which are grouped under the general head of stress, there appears to be a physiological susceptibility that begins to be evident in the teens and does not decline until the late twenties. This is reflected in the age distribution of death rates from this disease which, disregarding the high rate in the first year of life attributable largely to risk, reaches a peak in these age groups. The secondary peak of so-called late adult tuberculosis at around age 50 that has become apparent in the last three decades is another matter which is not relevant here. The physiological basis of heightened susceptibility to this disease of the young adult is not under-

The greater susceptibility of the aged to pneumonias is generally regarded as an expression of an accumulation of degenerative changes which find one expression in this way. It has not been possible to associate this susceptibility with specific physiological changes, but failure to accumulate immunities to microorganisms such as pneumococcus and streptococcus during the life history of the individual, because these immunities are transient, is no doubt a factor, but hardly a differential one.

Study of the effects of age on the susceptibility of experimental animals to tubercle bacillus³⁰ and streptococcal¹³⁶ infections has demonstrated significant effects of age; the effect on the susceptibility of the guinea pig to tuberculous infection appears to be similar to that in man. Age is a factor also in the susceptibility of mice to Coxsackie⁶³ and variola⁷⁰ viruses; and in experimental herpes infections the macrophage appears to be an important factor.⁵⁶

A consequence of the differences in re-

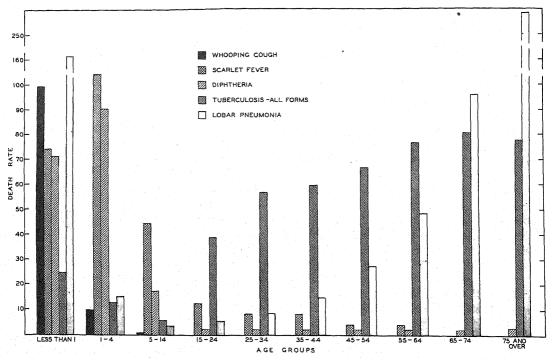

Figure 58. The age incidence of certain infectious diseases. Note the predominance of the diseases of childhood in the early years, the increase in tuberculosis in the young adult years, and the marked increase in lobar pneumonia with advancing age. Scarlet fever rate multiplied by a factor of 40 and diphtheria rate by a factor of 10 for comparative purposes. (Data from the reports of the Bureau of Census.)

sistance, or acquired immunity, to various pathogenic microorganisms associated with age groups is that the prevalence of disease, but not necessarily infection, is a function of the age distribution of the population (Chap. Ten).

Sex. A number of diseases exhibit a difference in sex incidence; pneumonia and epidemic meningitis, for example, are more common in males than females, while scarlet fever, typhoid fever, and others occur somewhat more frequently in females. Except for a few years in the 41-year period 1900-1940, the death rate for white female youths has been consistently lower than that for males, though the reverse has been true for the nonwhite population in this country. In the decade 1931–1940 the gap between the female and male in the nonwhite population was closed, and in 1940 the female and male death rates for nonwhite youths were exactly the same, at 5.0 per 1000. Corresponding rates for the white population were 1.4 for females and 2.0 for males. In the case of tuberculosis, variability in the agespecific mortality rates indicates a differential response on the part of the sexes. A sex differential is also indicated by the aftermath of the 1918 influenza epidemic, which appears to have had a more unfavorable effect upon female mortality than that of males in the 15- to 24-year age group, as indicated by the relatively high female death rate for all racial groups for several years after the epidemic.

It has been suggested that this difference between the sexes might result from resistance having some of the attributes of a sex-linked character, or, since differences in sex incidence are most pronounced during and after puberty, something in the nature of maturation immunity may be involved. There is no sound evidence to support the first of these hypotheses. Regarding the second, a certain amount of experimental evidence has been reported, the most precise relating to skin permeability, which has been found to be greater in female rabbits than in males. It has also been shown that female chicks are significantly more susceptible to infection with the chicken malaria parasite, *Plasmodium gallinaceum*,

than are males; treatment with male and female sex hormones did not affect the differences between the two. Any explanation of the observed sex differences must, of course, take into consideration other factors such as occupation, risk of exposure, and the like.

Climate and season.88, 119 That both climate and the season of the year exert marked effects on the incidence of and mortality in a number of infectious diseases is well known. In tropical climates, for example, the acute upper respiratory infections are not so common as in the temperate climates, but the dysenteries are more common in the tropics than in the temperate zones. The seasonal incidence of the infectious diseases is also common knowledge; meningococcus meningitis occurs predominantly in the winter and spring, poliomyelitis in the late summer and early fall, and so on. One of the most striking relationships of season to incidence of disease is that of cholera: the epidemic season coincides with hot weather and shows a remarkable correlation with precipitation and relative humidity. It is said that in the tropics, diphtheria is a rare disease and scarlet fever seldom occurs. Yet studies on the age incidence of positive Schick and Dick tests, indicative of immunity to these diseases, have shown that inapparent immunizing infections are quite as common as in temperate climates.31

In a great many instances the influence of climate and season upon the incidence of disease may be attributed to opportunities for transmission of the causative organism, such as crowding in poorly ventilated rooms, seasonal or geographic occurrence of an insect vector, and so on, but in others the factors responsible for seasonal incidence are unknown.

There is a good deal of evidence which substantiates the opinion that resistance varies with season, temperature, and similar factors. For example, the intensity of the brain reaction of mice inoculated with St. Louis encephalitis virus and of guinea pigs inoculated with endemic typhus rickettsiae has been found to be the greatest in summer and the least in the winter over a period of years; mice adapted to existence in a moist heat have been found only one-quarter as resistant to infection with hemolytic streptococci as those adapted to a cool environ-

ment; the morbidity and mortality rates in murine typhus infection in mice are affected by environmental temperature; and the resistance of mice to pneumococcus infection is similarly affected. On the whole, chilling reduces resistance to infection in experimental animals. 10, 57, 91, 129 In at least some instances seasonal variation in resistance may be correlated with diet (see below). It is not improbable that future investigation will yield systematic knowledge of the effect of climatic factors on susceptibility to disease.

General physiological well-being. Whatever resistance to disease an organism may possess by virtue of species, race, and the like, is profoundly influenced by its general physiological state. In general, resistance is at its height when the organism is functioning normally in every respect and is reduced by a variety of factors which interfere with and alter the normal physiological state. In some cases previous infection may reduce resistance to such a point that infection with the less virulent bacteria may take place, as in secondary infections; in others, functional disorders such as diabetes bring about a reduction in resistance to infection.9 More common, however, are the deleterious effects of inadequate diet and fatigue.

Nutrition.24, 101 The relation between susceptibility to infection and faulty nutrition has been of considerable interest in connection with the study of deficiency diseases. There is little doubt that nutritional status is of practical significance to the incidence of and mortality in infectious disease. The general problem has not responded to experimental study as readily as might be supposed. In a great many instances inanition is not clearly separable from a specific deficiency, such as a vitamin or amino acid deficiency, and results are complicated by such "side reactions" as dehydration resulting from reduced water intake by animals on certain deficient diets. In general, however, it seems to be clear that diets qualitatively and quantitatively inadequate may predispose to bacterial infection. The reduced resistance appears to be associated with a reduced humoral immune response, but this is in part at least compensated for by an accentuated phagocytic response to infection.

The importance of adequate protein intake has been emphasized by Cannon and his co-

workers, ¹⁴ and they have shown that depletion of the protein reserves of experimental animals by maintenance on low protein diets interferes markedly with antibody formation, *i.e.*, the synthesis of immune globulin. While antibody formation is significantly interfered with by moderate protein depletion, a severe depletion also interferes with the normal functioning of the cellular defense mechanisms as evidenced by reduced phagocytosis.

Other than this, just how malnutrition brings about a reduction in resistance is not known; present information indicates that the effect is a general one. It is of some interest that this unfavorable effect is not limited to the undernourished individual but may be transmitted to offspring. Experimental studies have shown, for example, that the diet of mice, genetically homogenous in resistance to an infection, affects the resistance of offspring to a greater degree than the diet of the offspring themselves. In this connection, statistical studies have suggested that the mortality rate during adult human life are in part a function of nutritive and other elements of the environment of childhood; in other words, the effect may be a delayed one, but the evidence on this point is not altogether indubitable. 16

The marked reductions in resistance associated with inadequate diets are in no sense specific; resistance to infection in general is reduced, and there is no relation between lack of a single dietary factor and susceptibility to a particular infection. A number of attempts have been made to demonstrate such a relation; ascorbic acid, for instance, has some small capacity to neutralize diphtheria toxin, but vitamin C deficiency does not predispose to infection with the diphtheria bacillus any more than with other organisms, such as the tubercle bacillus.

The apparently contradictory observation that resistance to infection with a number of the viruses is increased by inadequate diet has been made by a number of workers. That it is not completely inconsistent with the lowered resistance associated with protein depletion and other dietary deficiencies is indicated by the consideration that the viruses are obligate intracellular parasites; possibly a healthy cell is of primary importance to multiplication of the virus and the depleted cell is an unfavorable medium for development, thus masking, so to speak, the

lessened immune response associated with nutritional deficiencies.

More specific evidence in this connection has been reported for certain bacterial infections. It has been pointed out elsewhere that selection of virulent variants of a challenge microorganism may occur in vivo: virulent threonine-requiring variants of Sal. typhimurium are so selected by the animal given additional threonine.84 It has been found also that an induced variant of Sal. typhi having complex nutritive requirements showed at the same time reduced virulence for mice. The supposition that the animal did not supply the required nutrients in adequate amount was substantiated by the observation that full virulence was restored when the animals were given supplemental amounts of the nutrients required by the bacteria - purine, p-aminobenzoic acid, and aspartic acid. Similar results have been obtained with purine-requiring variants of Friedländer's bacillus, and seasonal variation in virulence could be correlated with the nutritional state of the animals.3, 4, 13

Fatigue. It has long been known to the clinician that bodily rest is a valuable adjunct to the treatment of disease, and there is clinical evidence which suggests that resistance to the initial infection may be reduced by excessive fatigue. Experimental evidence on this point is scanty and to some degree conflicting, but it is probable that the unfavorable effect of fatigue on normal physiological well-being is reflected to some extent in an increase in susceptibility to infection. The normal white rat, for example, is highly resistant to anthrax, but when exhausted by work in a treadmill, becomes susceptible. Latent Sal. enteritidis infections in the same experimental animal may be activated by fatigue to such a degree that the outcome is fatal. Exercise has been found to exacerbate intrapleural tuberculous infection in the guinea pig by increasing dissemination of the infection, 12 but, curiously, stressed monkeys have been found to be more resistant to poliomyelitis.71

Other mechanisms operative in the resistance associated with general physiological well-being are obscure. Studies on resistance to the common cold in population groups made by subjecting the incidence data to an analysis of variance among groups have strongly suggested that a constitutional factor, as yet undefined, is operative in the eti-

ology of the clinical infection. There is evidence too that the capacity to maintain effective circulation and the ability to withstand the effects of sudden temperature changes are associated with resistance to experimental infection. The adverse effects of sudden changes in temperature and humidity on the organism, reflected in changes in the nasal mucosa, are, perhaps, a manifestation of temperature shock. Attempts to associate such shock, vitamin deficiencies. fatigue, and other elements of the nonspecific resistance in health with specific defense mechanisms, such as the capacity to form antibodies, have not been uniformly successful.

The external defenses of the organism. The cellular organization of the animal body is a closed system with respect to the outside environment, from which it is separated by the skin, mucous membranes, and intestinal mucosa. These structures, generally impermeable to particulate material of the size of bacteria, constitute the first line of defense against invading microorganisms and one that is, for the most part, highly effective. While mechanical obstruction contributes in no small part to the efficacy of these barriers, both skin and mucous membranes also play an active part in the protection of the organism against bacterial invasion.

The skin. As a rule, the unbroken skin presents a more or less impassable barrier to microorganisms. Bacteria are found normally on the skin between the superficial horny cells, but ordinarily are not able to penetrate deep into the tissues unless favored by some cutaneous injury, such as a wound or burn. Direct penetration of the skin is, however, indicated as the initial route of infection in certain infectious diseases such as Weil's disease (leptospirosis) and possibly syphilis. Also, infection via the ducts of the sweat glands and the hair follicles is strongly suggested in other instances, notably the staphylococcal and streptococcal infections resulting in acne, impetigo, boils, etc., and has, in fact, been demonstrated experimentally with these pyogenic bacteria.

The skin seems not to be a completely inert surface on which bacteria die largely as a consequence of drying. On the contrary, healthy intact skin exerts demonstrable bactericidal activity on those microorganisms not normally present, but the activity is not as pronounced as once supposed. It is re-

garded by some as a consequence of the bactericidal activity of unsaturated fatty acids, especially oleic acid, present in the sebaceous secretions. This activity is inhibited by serum albumin; this may be of some practical significance as regards skin immediately surrounding a burn or other lesion producing a serous exudate. Possibly related is the fungistatic action of the free saturated aliphatic acids in the hair fat of adults. Bacteria normally present upon the skin, such as the white staphylococci, are not appreciably reduced in numbers when swabbed on the clean skin, a fact which probably accounts for their constant presence on the body.

The conjunctiva. Bacteria and dust particles settling in the eves are removed relatively rapidly by the mechanical flushing effect of the tears. The lacrimal secretions contain the enzyme lysozyme, 100 which is also present in certain tissue extracts, is identical with the avidin of egg white, and has been prepared in crystalline form. As described elsewhere (Chap. Three), this enzyme decomposes the cell walls of certain bacteria with the formation of protoplasts, but the protoplasts are ordinarily unstable and the antibacterial effect of this activity is bacteriolytic. Relatively few microorganisms are susceptible to this activity. One, Micrococcus lysodeikticus, is exquisitely sensitive and is destroyed by tears in dilutions as high as 1:40,000.

The nose, nasopharynx, and respiratory tract.^{5, 47, 138} Bacteria and other particulate material present in inspired air are rapidly removed by passage through the tortuous nasal passages lined with mucous membrane to whose moist surface they cling. In this way air is largely freed from bacteria in the upper respiratory passages, those that pass the larynx are caught in the bronchi, and few reach the ultimate ramifications of the bronchioles. The process is so efficient that expired air contains almost no bacteria except those that are expelled in droplets by sneezing, coughing, etc.

The moist film which covers the mucosa of the upper respiratory tract and in which bacteria removed from inspired air and those arriving via the lacrimal secretions are embedded consists of mucus, a thin, highly viscid substance that, in a sense, constitutes a continuous web or membrane overlying the surfaces within the nose, sinuses, pharynx,

and esophagus. This film of mucus is in constant motion as a result of the activity of cilia which sweep the mucus and its bacterial content toward the oropharynx, where it is swallowed. The exchange of mucus is rapid: that covering the posterior two-thirds of the nose is replaced every 10 or 15 minutes, while that over the anterior third is removed every hour or two. Although mucus itself has no bactericidal activity, when combined with ciliary activity it constitutes a remarkably efficient means of ridding the upper respiratory passages of bacteria. 62 Particles above 7 μ in diameter which are inhaled are retained in the upper respiratory passages of the rabbit, about half the particles 3 μ in diameter are similarly removed, and the remainder, plus practically all those 1.5 μ in diameter and smaller, penetrate into the lungs (see also Chap. Ten). The bacteria that penetrate the respiratory passages into the alveoli are phagocytosed by macrophages. 44, 45

Lysozyme is, of course, present in the nasal mucus, and it has been observed that the normal serous secretion of the nose contains a virus-inactivating agent distinct from lysozyme. The activity is virucidal for the influenza and certain other viruses inactivated by sodium deoxycholate, but what part it plays in resistance to infection is not clear.

The mouth, stomach, and intestinal tract. The mouth contains a predominant normal bacterial flora and a minor transient flora. The former consists of microorganisms which have established positions between the teeth, on dental plaques, in the crevices between the teeth and the gums, etc., while the latter represents a constant contamination. Both are subject to constant depletion because of the flushing action of the saliva. Saliva is thought by some to be mildly bactericidal, possibly because of the presence of small amounts of peroxide accumulating as an end product of microbial respiration. The removal of bacteria is, however, largely a mechanical process. The microorganisms flushed to the back of the mouth meet with those from the nose and, with them, are swallowed.

Bacteria reaching the stomach are subject to the strongly acid environment of the normal gastric juice, and there is no doubt that the great majority of them are destroyed there. Some do, however, reach the intestinal tract, perhaps because they are embedded

in solid particles of food and thus protected or because they are able to withstand a short exposure to the bactericidal action of the gastric secretions. Generally, very few viable bacteria are found in the stomach, but the numbers of microorganisms increase in the small intestine with the rise in pH from the duodenum to the ileum. The large intestine contains great numbers of bacteria derived not only from the upper levels of the intestinal tract but also from the multiplication of bacteria present in the intestines as normal inhabitants. As in the respiratory passages, mucus plays an important part in the mechanical removal of bacteria. Here. however, the mucus does not form a uniform coating over the intestinal mucosa but is present as a meshwork. The villi free themselves from particles by movements which bring them in contact with the mucus to which the particles, including bacteria, adhere. The mucus, with the embedded microorganisms, is rolled up into small masses and moved outward by the peristaltic movements of the bowel. Bacteria, then, which enter the mouth and upper respiratory tract are eventually extruded with the feces.

Microorganisms present in the lumen of the bowel, including those making up the normal intestinal flora, are, for all practical purposes, outside the tissues of the body. This flora contributes, in itself, a protective mechanism with which the invading pathogen must compete successfully to establish a focus of infection (see below). Penetration of the tissues from the bowel, as in typhoid fever, is usually via Peyer's patches into the lymphatic system and the blood stream through the thoracic duct. Ordinarily this barrier is a highly effective one, but one of the effects of whole-body ionizing irradiation is a breakdown of this barrier, followed by a generalized invasion of the tissues by bacteria from the intestine, and the immediate cause of death in radiation sickness may be fulminating bacteremia.

The genital tract. The normal genital tract is remarkably free from bacteria. The urethra in both male and female is normally sterile, a consequence, perhaps, of the flushing action of the slightly acid urine. The few bacteria that may be present are confined to the region of the meatus. The normal vaginal secretion is acid and is markedly bactericidal toward most species of bacteria.

Internal defenses. On gaining access to

HORMONES 287

the tissues, the pathogenic microorganism needs to establish and maintain foci of infection, and a number of internal factors in resistance may be distinguished. The relative susceptibility, or resistance of tissues that finds expression as the cytotropism of microorganisms in naturally occurring infections has been described elsewhere (Chap. Four). Other factors include the relevant physiological responses subject to hormonal regulation, and the antimicrobial activities demonstrable in tissues and organs.

Adrenocortical hormones. 58, 114 Hormonal imbalance, and consequent disturbance of a wide variety of functions, is, in general, associated with increased susceptibility to infection. The elements of natural resistance may thus be inferred from effects which result in increased susceptibility. Such effects are not direct, in that the internal secretions affect the microorganism directly, but are concerned, though not necessarily linked, with physiological patterns of response to stimuli such as those provided by the pathogenic microorganisms and their products.

The well-known predisposition of the diabetic to infection, such as gangrenous disease of the extremities, is perhaps to be associated with circulatory disturbance and illustrates the indirection of the relation of hormonal imbalance to natural resistance. Similarly, hypothyroidism results in reduced resistance to experimental tuberculosis, 67 but the effect on the specific immune response is less clear and appears to vary with animal species. 105 Of the hormones, those of the adrenocortical group have been of the greatest interest because of the marked depression in resistance that they produce. In essence, this effect is a consequence of a depressing effect on the inflammatory response and the activity of the cells of the macrophage (reticulo-endothelial) system and emphasizes the significance of these cells in natural resistance. The cellular response to infection is qualitatively the same in the normal and specifically immune animal but is markedly accelerated and accentuated in the latter, and is considered elsewhere (Chap. Fourteen) in this connection. Here the effects of this group of hormones may be regarded as both broadening and modifying the contribution of this system of cells to resistance, as well as indicating the significance of other, probably less important, factors.

The effects of administration of adrenocortical hormones on infections have been summarized by a number of reviewers. The administration of ACTH or cortisone to patients with acute febrile illness usually leads to a prompt defervescence in proportion to the severity of the symptoms, but at the same time there is not only no improvement with respect to the microorganism, and the infection may spread and secondary infections appear almost asymptomatically because of the effect of the hormone. Herpes simplex appears to be one of the exceptions, for topical application of corticosteroids, common in ophthalmology, to herpetic infections of the eye results in an exacerbation of the disease process with the spreading destructive involvement which has often resulted in perforation of the cornea.⁵⁴ Administered to normal animals, these hormones depress natural resistance to experimental infection except in those cases, such as pneumococcal infection in the mouse, where susceptibility is already maximal, and lead to the activation of latent infections if these are present. Further, when given in combination with antibiotics, the efficacy of the chemotherapeutic agents is reduced, emphasizing the significance of the role of host factors in successful chemotherapy. These hormones also accentuate the activity of endotoxins, as indicated earlier in connection with the Shwartzman phenomenon, not by affecting the toxin directly, but by interfering with the cellular response and detoxifying mechanisms. Pre-existing antibody is not affected, nor is the antigen-antibody union, but antibody formation is depressed by these hormones. It is, therefore, not surprising that the appearance of infection is a major reason for discontinuance of cortisone or ACTH therapy initiated for other purposes or that the immediate cause of death in spontaneous hyperadrenalism (Cushing's syndrome) is often infection, and the death rate from this disease has not been altered appreciably since the introduction of antimicrobial chemotherapeutic agents.

Organ and tissue factors.^{52, 112} The possible presence of antimicrobial substances in various tissues and organs is a matter of considerable interest but has not been extensively studied. Two kinds of substances, the one water- or saline-soluble and the other lipid in nature, have been prepared from a wide variety of tissues.

The water-soluble substances found in saline extracts of hog pancreas and thymus and calf thymus are basic polypeptides containing relatively large amounts of lysine or arginine. These substances have, in the aggregate, antibacterial activity on microorganisms such as the anthrax bacillus, streptococci, staphylococci, and tubercle bacilli, differing from one to another in activity. Similar polypeptides are also found in inflammatory exudates in the lung which are active against pneumococci. It is not fully established that all of these substances are not artifacts formed by, for instance, hydrolysis of histones during extraction. Spermine, found in semen and in tissues such as beef kidney, has antibacterial activity against tubercle bacilli. Substances of lipid nature, soluble in organic solvents and slightly soluble in water and saline, have also been isolated from the liver and spleen of rats and guinea pigs and have antipneumococcal activity which is directly related to the susceptibility of the animal species to infection with these bacteria. In most instances such a direct relationship between antimicrobial activity and the susceptibility of the animal from which the tissue extract was derived has not been established.

Interferon, the activity produced by tissue culture cells in response to myxoviruses, and perhaps others, and described earlier (Chap. Four), is not, like the tissue factors described above, pre-existing. While some activity is demonstrable *in vivo*, any contribution such activities may make to natural resistance is as yet uncertain.

Properdin.^{89, 130.} This high-molecular-weight antigenic fraction of human euglobulin, representing no more than 0.03 per cent of the total serum protein, was described by Pillemer and his co-workers as having marked antimicrobial activity against gram-negative enteric bacilli and the Newcastle disease virus when combined in the properdin system consisting of properdin, all four components of complement (Chap. Thirteen), and magnesium ions.

Properdin is inactivated by irreversible combination with a substance known as zymosan. Zymosan is the insoluble residue of yeast cells which have been digested with trypsin and extracted with water and alcohol, and it consists largely of carbohydrate from the yeast cell wall. The properdinzymosan complex selectively inactivates

the third component of complement (C'_3) in the presence of magnesium ions at 37° C. but not at 17° C. The activity is titrated by preparing a serum lacking in properdin but containing C'_3 , by treatment with zymosan at 15 to 18° C. The unknown serum, or body fluid, etc., is then titrated for properdin by mixing varying dilutions with the properdin-free serum plus zymosan, incubating, and titrating for C'_3 in the usual hemolytic system. A unit of properdin is defined as the smallest amount which will remove, as the properdin-zymosan complex, 120 units (50 per cent) of C'_3 .

The nature of properdin is obscure; *i.e.*, whether it is a distinct molecular species having multiple properties or an aggregate of substances is not known. Though originally described as a normal serum component associated with an antimicrobial activity distinct from that of the antibodycomplement system (Chap. Fourteen), it now seems that serum bactericidal activity is dependent upon the presence of antibody occurring as natural antibody in normal serums (Chap. Fifteen). 80 Thus the relation between properdin and natural resistance has become quite uncertain. 102

Cellular response. 29, 46, 96, 137 When the body tissues are penetrated by microorganisms an inflammatory reaction and characteristic cellular response occurs. The area is invaded by phagocytic cells, first heterophils or polymorphonuclear leucocytes, and then by macrophages which can develop into fibroblasts, functional in the repair process. This kind of reaction constitutes one of the most important aspects of resistance, the inflammatory response in the nonimmune animal constituting an element of resistance. In the immune animal this response to the homologous microbial antigen is qualitatively the same, but the reaction is markedly accelerated, and is considered elsewhere (Chap. Fifteen).

Normal flora.⁹⁷ A microorganism somewhat better able to resist the defensive mechanisms of the host but at the same time unable, except when resistance is reduced to a low level, to invade the body tissues, may exist in conjunction with the host as a part of the latter's normal flora. The staphylococci which are able to resist the bactericidal action of the skin are almost invariably present on these surfaces and are regarded as normal inhabitants. The

scanty bacterial flora of the vagina, on the other hand, is composed almost entirely of aciduric bacteria, and the bacterial types present in the intestines are determined to a considerable extent by the type of food material present, *i.e.*, the diet of the host, and by the pH of the various intestinal levels.

Certain kinds of bacteria, such as lactobacilli, spirochetes, various cocci, and the like, exist in the mouth in the interstices between the teeth and in and under tooth plaques and constitute a normal flora characteristic of this region. The bacteria commonly present in the nose and throat consists of still different forms, such as pneumococci. Friedländer's bacillus, and green and hemolytic streptococci. These organisms, while in a sense a normal flora, are not so well established as the flora of some other regions, and the nature of the microorganisms present may be determined in large part by the kind of bacteria which are constantly entering the upper respiratory tract.

As long as the resistance of the host is maintained at a sufficiently high level, the bacteria constituting the normal flora do no harm. If, however, resistance is reduced in some manner, or unbalanced by administration of antibiotics such as the tetracyclines as noted earlier (Chap. Six), the more virulent forms may invade the tissues and set up an infection. The congestion of the nasal mucosa and the consequent interference with ciliary activity and the movement of mucus, which follow the temperature shock of chilling, not infrequently make possible infection by bacteria such as hemolytic streptococci or pneumococci, which are already present.

The normal flora also functions as a part of the resistance complex, especially when the portal of entry of the pathogenic microorganism is the intestinal tract. The pathogen must compete successfully with the normal flora of the bowel to set up a focus of infection in the initiation of the disease process. The protective effect of the normal flora, which may range from competition to antagonism, may be very considerable. The antagonistic relationships involved are complex, being based on the interrelation of the metabolic activities of the competing microorganisms. 33, 49, 83 For example, enteric infection of experimental animals with human enteric pathogens may be difficult to establish, but when the pathogen is made drug-resistant and inoculated intragastrically with the drug, the microorganisms of the normal flora are inhibited, while the drug-resistant pathogen is not and is able to establish an infection.^{32, 76, 77}

Germ-free animals.87, 94, 120 The adaptation of microorganisms to a parasitic existence, indicated by the tendency of long-established diseases to become less severe and at the same time more prevalent, has been considered elsewhere (Chap. Seven). The corollary is whether or not the host, through long association, becomes similarly adapted to the presence of the microorganism, even to such a degree that the relationship becomes a symbiotic one. In certain cases the presence of a parasitic microorganism bears a significant relation to the assimilation of food by the host; such, for example, is the case with respect to the leguminous plants and the root nodule bacteria, and the herbivorous animals and cellulose-decomposing microorganisms of the rumen. Whether the abundant intestinal flora of man and other animals has some analogous relation to the host has been of very considerable interest. 124

Nuttall and Thierfelder early showed that guinea pigs, removed by cesarean section and kept in a sterile environment, survived for 10 days or so, but Schottelius was not successful in rearing bacteriologically sterchicks. Nutritional inadequacies of the chick diet apparently accounted for these results, for it was later shown that chicks could be raised for as long as 40 days in a bacteria-free environment. Modern studies began largely with the work of Reyniers and his colleagues, and have shown that not only chickens, but also a wide variety of animals such as guinea pigs, rabbits, and rats may be reared and bred in the complete absence of bacteria. Nutritional requirements are considerably more complex than for the conventional experimental animal, and natural immunity is limited, illustrating the significant role of the active immune response in the complex commonly considered to be resistance.

THE EPIDEMIOLOGY OF INFECTIOUS DISEASE

Whatever the pathogenic powers of a microorganism and the efficiency of the defensive mechanisms of the host, an essential preliminary to the production of infectious disease is a meeting of the parasite and its prospective host. In some instances in which the bacterium is naturally saprophytic, it enters the body by accident, so to speak; such, for example, appears to be the case in tetanus, gas gangrene, and similar infections. In most instances, however, the microorganisms that produce disease are more or less closely adapted to a parasitic existence and pass from one animal body to another with only a relatively brief sojourn in the external world. In general, then, the transmission of infection is a process in which the causative microorganism is transferred, either directly or indirectly, from a diseased to a healthy susceptible animal.53

The elucidation of the mechanisms involved in this transfer is a matter of considerable importance. If the sequence of events that precedes infection is known, it may be, and often is, possible to interrupt it at its most vulnerable point and thereby control the spread of disease. Disease is by no means entirely a matter of host resistance and microbic virulence: it is, in a very real sense, the outcome of the interaction of the host and parasite populations. It is at this point that the study of the infectious diseases transcends the microbiology of clinical medicine, with its emphasis on the individual case, and assumes broad biological significance as a problem in interspecies competition.7,37

The equilibrium that tends to become established between the host and parasite populations is an unstable one in that the factors which determine it-i.e., the character of the host population in particular and possibly that of the parasite population. as well as the environmental factors which affect their relationship—are constantly shifting, and the equilibrium ever has a tendency to establish itself at a new level. The shift may be a sudden and violent one whose outward manifestation is an explosive outbreak of disease or, less commonly, may take the form of a gradual increase or decrease in the incidence of the disease.

The factors associated with the maintenance or shift of this equilibrium are the subject matter of epidemiology. 14, 30, 31, 44, 48 The term epidemiology is best regarded in this broad sense and therefore includes the study of the transmission of endemic disease, i.e., disease which has a low incidence but is constantly present in a population, as well as the study of epidemic disease, i.e., disease of high morbidity which is only irregularly present in clinically recognizable form. In this connection it may be noted that the term pandemic is often applied to an epidemic of unusually great proportions. These categories, although useful, are not mutually exclusive; a disease endemic in a community may, at times, attain the proportions of an epidemic and later subside to an endemic level.

Essential to knowledge of the epidemiology of disease are certain characteristics of the etiological agent and of the clinical infection which determine the possible channels of transmission. The more important of these are:

- (1) The route by which the infective agent enters the
- (2) The route by which the infective agent leaves the
- (3) The resistance of the microorganism to the deleterious effects of the outside environment
- (4) Presence or absence of an intermediate host
- (5) The relation between frank, clinically recognizable disease and the discharge of virulent microorganisms from the body

These are most readily and satisfactorily determined by direct study of the etiological agent under controlled conditions as well as the pathogenesis of the naturally occurring disease. When the etiological agent is unknown, however, a first approximation of these properties may be inferred with surprising confidence from the observed epidemiological behavior of the disease. For example, although the famous Broad Street Pump epidemic occurred prior to the discovery of the etiology of cholera, the indirect evidence plainly indicated to Snow that the infective agent left the body in the feces and entered the gastrointestinal tract via the contaminated well water.40

The carrier. With regard to the last characteristic listed above, additional explanation is desirable. In the early days of microbiology it was assumed that the contact of host and parasite could have only one or the other of two outcomes; either no infection occurred, owing presumably to high resistance on the part of the host, or clinically characteristic disease developed in the individual. Subsequently it became clear that an intermediate state, the establishing of a symptomless infection, may occur. Such infections are, of course, inapparent and concealed and may be demonstrated only by isolation and identification of the infectious agent. An individual so infected is termed a carrier.

Two types of carriers are commonly differentiated, the casual carrier who harbors the microorganism temporarily, a matter of a few days or weeks, and the chronic carrier who remains infected for a relatively long time, sometimes throughout life. Such individuals serve to disseminate the infectious agent. In the first group are the great majority of carriers of the diphtheria bacillus, meningococcus, pneumococcus, certain streptococci, etc., and the second includes carriers of certain of the enteric bacilli, especially the typhoid bacillus. A third type of carrier is often differentiated, the convalescent carrier, who remains infected for a greater or lesser length of time after recovery from the disease. These last do not fall into the category of concealed infections. Sharp separation is sometimes not possible, however, for the casual or chronic carrier may. in fact, be convalescent from the disease in a form either atypical or so mild as to go unrecognized (ambulatory cases).

While it is now commonplace to recognize the existence of the carrier state, the implications of the general principle that infection may occur without disease are frequently neglected. Thus it follows that clinically apparent infections may constitute only a part, in some instances only a very small part, of the infections continually taking place. Clearly, then, if an important proportion of the infections are of the concealed type, a reasonably accurate estimate of the extent to which the infection is disseminated in the host population cannot be arrived at on the basis of cases of the disease. The implications of this are several. For example, diseases which occur sporadically and do not seem to be easily or often transmitted from the sick to the well, such as poliomyelitis, meningococcus meningitis, and pneumococcus pneumonia, may be as widely disseminated and readily communicable as measles or the common cold, but the clinically distinctive disease is the exception rather than the rule. Furthermore, the rise or decline of infectious disease or its age or geographical distribution may not reflect a corresponding variability in the prevalence of the infection but rather may be a consequence of variation in the casecarrier ratios. Though here inferred from the observed occurrence of the carrier state, none of these possibilities remains purely hypothetical for all have been found to exist. Thus, carriers of virulent pneumococci do not occur predominantly in the higher age groups, or diphtheria bacillus carriers in the schoolchild, where the morbidity of these diseases is highest; diphtheria bacillus carriers are as common in the tropics as in temperate climates despite the relative rarity of clinical diphtheria in the hot climates; and so on. In many other cases, such as that of poliomyelitis, such a situation is suspected but technically difficult to prove. It will be obvious, therefore, that the recognition of the carrier state and its implications is basic to sound epidemiological thinking and of primary importance to the understanding of the mechanism of spread of the infectious diseases.

EPIDEMIOLOGICAL TYPES OF INFECTIOUS DISEASE

On the basis of such fundamental information, the infectious diseases may be separated into a number of epidemiological types which, despite certain limitations, serve to illustrate the diversity of ways in which infection may be disseminated.⁵ A rough classification, based on the assumption that the human being is the recipient of infection and that the control of diseases of man is the point at issue, follows:

- (1) Diseases of lower animals transmissible directly to man (rabies, tularemia, glanders, etc.)
- (2) Diseases of animals or man transmitted by insect vectors in which
 - (a) The insect acts as a mechanical carrier e.g., the housefly (typhoid fever)
 - (b) The parasite multiplies in the insect vector (bubonic plague)
 - (c) The parasite is transmitted from one insect generation to the next by egg infection (spotted fever)
 - (d) The parasite undergoes a portion of its life cycle in the insect (malaria)
- (3) Diseases of animals or man transmitted indirectly (a) By water (the enteric infections such as typhoid fever and cholera)
 - (b) By milk (scarlet fever, bovine tuberculosis, undulant fever, etc.)
 - (c) By food (typhoid and paratyphoid fevers)(d) By inanimate objects or fomites, such as books and towels (scarlet fever, diphtheria, and the like)
- (4) Diseases of man transmitted directly
 - (a) By infective droplets—airborne infection (the respiratory diseases and others)
 - (b) By direct contact (the respiratory and veneral diseases in particular)

The epidemiology characteristic of a given disease shows, on the one hand, certain and sometimes close relationships to other similar infections, and, on the other, a certain variability which arises as a result of transmission in more than one way. The enteric infections, cholera, typhoid fever, and the bacillary dysenteries, are similar to one another in epidemiology but are

quite different in this respect from the respiratory diseases or the insectborne diseases. The epidemiology of typhoid fever, however, is variable within limits and depends to some degree upon whether the disease is waterborne, milkborne, or transmitted by food or contact. In the case of waterborne typhoid, the drinking water supplies the connecting link, and the ensuing epidemic, usually explosive and limited to the area supplied by the contaminated water, shows no respect for age, sex, or economic status. Milkborne typhoid, on the other hand, is geographically limited by the route by which the infected milk is delivered, exhibits an increased incidence in the lower age groups and among females and is somewhat more frequent among those of higher economic status. Foodborne infection is still more limited, often within a family group, with no discrimination as to age or sex.

Variation in the epidemiological character of a disease may also occur with changes in the behavior of the host population. For example, the age incidence of poliomyelitis has altered in the past few decades, with a shift to the higher age groups and disappearance of the marked preponderance in young children, coupled with an increasing frequency of epidemic outbreaks of the disease. The shift has been greater in the North than in the South in this country, greater in rural than in urban areas, and greater in the United States than in other countries. This shift is commonly interpreted as evidence of postponement of effective contact with the virus, and there is some evidence that this is associated with economic status; i.e., the shift is more marked in the higher economic brackets.3 The shifting pattern in the behavior of poliomyelitis is more complex than this, and is discussed in more detail elsewhere (Chap. Thirty-nine).

Airborne infection. Many of the diseases of man are transmitted as airborne infection in which suspended infectious material is inhaled. In contrast to the indirect transmission of disease by, for example, agencies such as water and milk, this kind of link between the source of infection and its recipient is not readily broken, and it has usually not been possible to control airborne infection in this way to any practical extent. Under natural conditions, the in-

fectious material may occur in finely dispersed form in air originating directly from the source of infection, or it may be present in dust that, on resuspension in air, is inhaled.¹⁸

Infectious clouds. It was postulated many years ago by Pflugge that diseases of the upper respiratory tract could be transmitted by droplets containing the microorganisms and expelled from the mouth and nose during coughing and sneezing. The droplets he studied were relatively large, greater than 0.1 mm. in diameter, and seeded the air for only short distances before falling to the ground. Since epidemiological considerations demanded airborne infection effective at considerable distances, Pflugge's "droplet infection" appeared relatively unimportant. In the early 1930's, however, the matter was reinvestigated, especially by Wells and his associates, and it was found that Pflugge's evidence was incomplete, in that under usual conditions of humidity droplets smaller than 0.1 mm. in diameter are rapidly reduced in size by evaporation to leave suspended nuclei containing microorganisms that may remain viable and infective for a matter of hours. The process of expulsion of such droplets in coughing, sneezing, and talking to give rise to such suspensions has been studied by Jennison²⁰ and is illustrated in the accompanying figure. An example of the significance of such spread is the description of "cloud babies," infants who disseminate infectious clouds of staphylococci, and play a significant part in the dissemination of infections in nurseries.11

Interest in inhalation infection markedly stimulated during World War II because of the possibility that airborne infectious materials might be used as biological warfare agents,22 and the subject has been studied in considerable detail.³⁶ Infectious agents may be finely dispersed in air under controlled conditions in the laboratory by means of atomizers or nebulizers, and the cloud so produced may be studied with respect to viable microorganisms, infectivity, and the like.55 It has been found that survival of bacteria in the ambient cloud is conditioned by relative humidity and the nature of the original suspending medium. While many of the microorganisms may be killed, it is possible to generate clouds containing large numbers of viable

cells. The infectivity of such clouds of pathogenic microorganisms may be tested by exposing experimental animals in appropriate chambers, 9, 19 and it has been found that infection is readily produced by inhalation of clouds of appropriate pathogens.

Assuming the presence of viable microorganisms in sufficient number in the cloud. their distribution following inhalation is determined primarily by particle size. As pointed out elsewhere (Chap. Nine), the upper respiratory tract is a highly efficient mechanism for the removal of particulate matter suspended in inhaled air through impingement of such particles on the wet mucous surfaces. In general, large particles are removed in the nasal area, while very small particles may not be retained at all, but exhaled. Eighty per cent of particles 1.8 μ in diameter, 50 per cent of 4 μ particles, and 20 per cent of 12 μ particles penetrate the nose; when the nose is bypassed by mouth breathing, 23 per cent of 1 μ particles, 38 per cent of 2 μ particles, 52 per cent of 3 μ particles, and 68 per cent of 5 μ particles are retained in the lungs.³² Total body retention is, however, greater than indicated by examination of the respiratory tract alone. Inhaled bacteria are also present in the esophagus and stomach. By the use of radioactive phosphorus as a tracer, it has been found¹⁵ that there is about a 30 per cent retention of 1 μ particles in the respiratory tree but a practically complete whole body retention of the theoretically inhaled dose, with the remaining 70 per cent predominantly in the gastrointestinal tract. The occurrence of inhaled material in the gastrointestinal tract is, of course, a consequence of the removal mechanism described elsewhere (Chap. Nine) in which mucus secreted in the upper respiratory tract is swallowed, and contained bacteria are eventually excreted with the feces.

A wide variety of laboratory procedures—ranging from pipetting and decanting of supernatants after centrifugation to opening freeze-dried cultures and the operation of blenders—generate aerosols. Infectious aerosols so produced probably account for the majority of accidental laboratory infections, and their control is a matter of both proper equipment and technique.^{34, 42, 52}

Infectious dust.³⁸ The source of pathogenic bacteria in dust is two-fold: the settling out of droplets containing them that are too

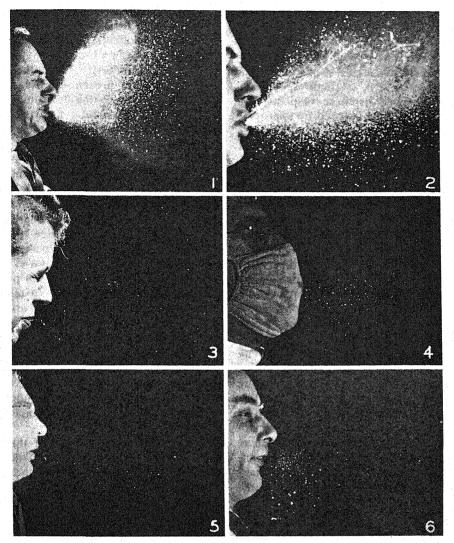

Figure 59. The atomization of mouth and nose secretions demonstrated by high speed photography. 1, a violent sneeze in a normal subject; note the close approximation of the teeth, resulting in effective atomization. 2, head cold sneeze; note the strings of mucus and the less effective atomization of the viscous secretions. 3, a stifled sneeze. 4, sneeze through a dense face mask. 5, cough; note the smaller discharge than in the uninhibited sneeze. 6, enunciation of the letter "f." (Jennison.)

large to remain suspended in air any great length of time; and contamination of objects, especially textile products such as handkerchiefs and blankets, with infectious secretions that, after drying, become infectious dust. For example, contamination of the environment with Streptococcus pyogenes by infected persons has been shown to be in part a contamination of dust. Present evidence suggests that the inhalation of airborne bacteria in dust may be quantitatively more important than that of directly expelled particles; i.e., dust is probably a more

prolific and constant source of contamination of air. Control measures directed toward the suppression of dust, such as the oiling of blankets and floors in infectious wards in hospitals, have been more effective in the control of infection than attempts to destroy bacteria in air, as by ultraviolet irradiation.

THE MICROBIAL POPULATION

The well-known variation in the severity and "contagiousness" of the infectious

diseases is a consequence of corresponding variation from one species of pathogenic bacteria to another in their ability to invade the body tissues and, once established, to produce clinical disease. As indicated elsewhere (Chap. Seven), a single species is potentially variable in these respects, for such variations can be induced by appropriate experimental manipulation. The possibility of such intraspecies variation in a bacterial population existing under natural conditions is one that has intrigued students of infectious disease for many years.

It is tempting to account for the genesis and rise of epidemic disease by assuming that the causative agent of a disease of endemic proportions gains in virulence by successive passage from person to person until its pathogenicity is so enhanced that an epidemic ensues. Similarly, a sojourn in a host population containing an increasingly large proportion of immunes might be expected to result in a diminution in the virulence of the microorganism and consequent subsidence of the epidemic. Furthermore, successive epidemic waves might conceivably result from periodic fluctuations in the virulence of the parasite. Unfortunately for such an explanation, there is little or no direct evidence that alterations in virulence play an important part in the evolution of single or secondary epidemic waves, and, in nature, microbial virulence appears to be a relatively stable character.

On the other hand, differences in the severity of a single disease from one epidemic to another are, in part, attributable to the existence of strains of the infectious agent which differ from one another in virulence. Benign and malignant smallpox referred to above is a case in point, and some workers believe that some strains of the diphtheria bacillus produce a more severe disease than others (Chap. Thirty). Although the bacillus varies from one strain to another, available evidence indicates that within a single strain virulence does not fluctuate to a demonstrable degree.

Possibly attributable in part to alterations in bacterial virulence are the changes in morbidity and mortality of some diseases such as scarlet fever, syphilis, and tuberculosis over long periods. In the case of scarlet fever the 25 years prior to 1830 was a period of very low death rates and was followed by a 40-year period of high death rates. Since

then the death rate has declined, and, though the incidence remains high, the case fatality is relatively low. In other diseases only a decline has been observed. Syphilis is no longer the scourge it was in the sixteenth century, and the present decline in tuberculosis began before the institution of preventive and therapeutic measures. In still other diseases, such as measles, no such long-term alterations in prevalence have been observed. Information is as yet too limited to assess these phenomena; possibly in some diseases there are long-term periodic fluctuations in bacterial virulence (this may be an artifact and represent only variations in the prevalence of virulent "epidemic" strains of the parasite), while in others an adaptive reduction in virulence or increase in resistance on the part of the host or a combination of both may play a part. Perhaps the most elegant example of this phenomenon has been illustrated by the attempt to control the rabbit population in Australia by the introduction of myxomatosis virus. Initially the rabbit population declined sharply, but with adaptation of the host and parasite, an equilibrium became established with essentially complete defeat of the initial objective. 13

In general, it may be said that, in the short view, the bacterial population, as it exists in nature, is remarkably stable insofar as its ability to produce disease in a host population is concerned. Although the severity of a disease may, and often does, vary from one epidemic to another, variation in virulence is not an important factor in the single epidemic wave. Over long periods, however, alterations in virulence may contribute to the changes in morbidity and mortality observed in some of the infectious diseases.

THE HOST POPULATION

In contrast to the relative stability of the bacterial population, the human population is highly variable in its resistance to infection, and the variation, attributable to both intrinsic and extrinsic factors, is not infrequently of such magnitude that its consequences are of considerable practical importance.

Since a population, human or infrahuman, is composed of individual organisms, it

follows that its character is determined by the nature of these individuals and their relations to one another, and its reaction to an external influence is expressed in terms of the aggregate of the reactions of its members. The response of a human population to an infectious disease is, of necessity, measured in terms that are composites of the responses of the individual members of the population - in short, by some method of counting. Such counting is, of course, the basis of statistics, and the statistical method, with its ramifications and refinements, is a powerful tool which makes possible the study of the response of human populations to disease – a response which is measured in terms of rates, ratios, life tables, and similar numerical devices.10

Intrinsic factors. Of the intrinsic factors which determine the response of a human population to an infectious disease, one of the most important is age distribution. The quantitative predominance of the lower age groups characterizing an immature population declines with population growth while the higher age groups correspondingly increase. As a consequence, the diseases of childhood and early adult life, such as

diphtheria, tuberculosis, and the like, are relatively prevalent in an immature population but become progressively less so with the passage of time, while the diseases of old age increase in incidence with the maturing of the population. The frequency of an infection is expressed as a rate, either as the number of persons infected in a given unit of time, i.e., incidence, or as the total number of persons infected at any one time, i.e., prevalence. Correction of morbidity and mortality rates is a practical necessity and is made either by the use of specific rates, i.e., the proportion of cases or deaths within a specified age group, or by the use of standardized rates which are not the observed rates but rather what the observed rates would be if the age distribution of the population were that of a standard or reference population.*

^{*}Two standards have been used in Europe: one, the population of Sweden as it existed in 1890; and the other, the population of England and Wales as shown by the 1901 census. The first is standard in age distribution only, while the second is standard for both age and sex. In this country the population of the entire country is usually taken as a standard, and the populations of states or other portions of the country compared or adjusted to it.

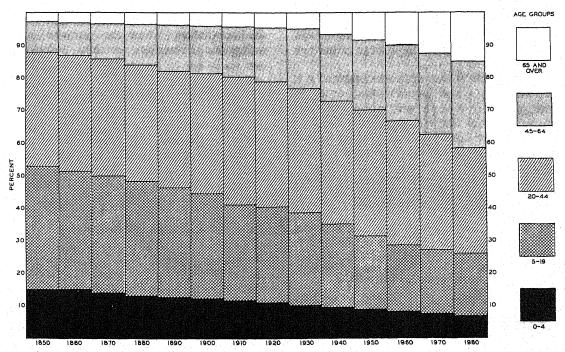

Figure 60. The age distribution of the population of the United States, enumerated from 1850 to 1960 and projected to 1980. (Data from the U. S. Bureau of the Census: Decennial Censuses, and Current Population Reports, Series P-25, No. 241, 1962. Compiled by the Population Research and Training Center of the University of Chicago.)

The sex distribution of a population and its racial composition are of somewhat lesser practical significance, although in some communities in the United States the high mortality rate of the Negro has necessitated the use of race-specific mortality rates.

Extrinsic factors. The extrinsic factors which alter the resistance of a host population to the spread of disease may exert their effects in either or both of two ways: first, by influencing the resistance of part or all of the individuals comprising the population, and, second, by influencing the relationships between individuals. Perhaps the most important factor in the first category is active individual immunity. If a sufficient portion of a population is immune to a disease as a result of artificial inoculation or recovery from an attack, the resistance of the entire group to epidemics of that disease is of a high order, a phenomenon which has been termed herd immunity. Other factors may reduce the resistance of the individual; in times of stress or calamity, for example, when relatively large groups are undernourished, fatigued and exposed to inclement weather, epidemic disease may spread with great rapidity.

Equally important to the resistance of a population to epidemic disease are the factors which determine the interrelationships of its members. Crowding in large gatherings

or the enforced close association arising from inadequate housing facilities obviously provides opportunity for the dissemination of respiratory and other diseases transmitted directly from man to man and, as well, certain indirectly transmitted infections, such as louseborne typhus fever. Similarly, the spread of enteric infections is, to a large extent, dependent upon sanitary facilities and the solution of the twin problems of water supply and sewage disposal. Group practices which support a large rat population make bubonic plague a potential menace, and the presence of large numbers of mosquitoes of the appropriate species allows the wide dissemination of malaria and yellow fever. These and other factors, political, sociological, or economic in nature, obviously exert no small influence on the resistance of a population to the spread of disease.39

THE INTERACTION OF HOST AND PARASITE POPULATIONS

It will be clear from the foregoing discussion that the interaction of the host and parasite populations is a highly complex phenomenon. Even assuming that the parasite population, when the parasite is a pathogenic bacterium, remains relatively

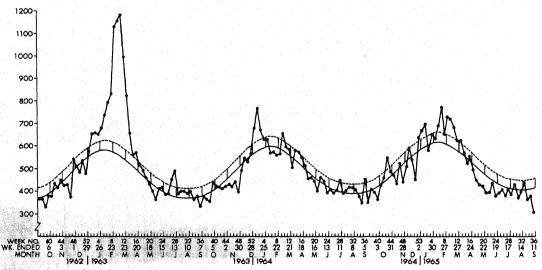

Figure 61. The effect of season on infectious disease as illustrated by the seasonal variation in death rate from pneumonia-influenza in large cities in the United States over a three-year period. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education and Welfare.)

constant in its ability to produce disease, the resistance of the host population is in a constant state of flux, and the equilibrium between the two is rarely a "steady state." As has been indicated, the relation between host and parasite populations is a part of the general problem of interspecies competition and has been studied at length. The infectious diseases of man constitute a series of special cases of the host-parasite relationship, differing from one another with respect to mode of transmission, incubation period, period of infectivity, immunity, case fatality, etc. The studies on infectious disease have taken two forms: one, the theoretical analysis of epidemic spread; and the other, the experimental investigation of controlled epidemics among populations of laboratory animals, i.e., experimental epidemiology.

Theoretical analysis. 29, 33, 41, 47 Theoretical treatment of the incidence of infectious disease in time consists of the formulation of mathematical models based upon the probability of contracting disease, independent of hypothetical variations in the virulence of the microorganism or the resistance of the host population other than as acquired immunity. A number of variables must be taken into account, including the effective contact or dose required to produce infection, the homogeneity of mixing infected and susceptible persons, infectivity of the recipient with respect to the latent or incubation period and to the onset and defervescence of the disease, and the effectiveness of the immunity associated with recovery. Of these, it is generally assumed that recovery from the disease gives an effective immunity, but the way in which the other relevant factors are presumptively defined prior to formulation in mathematical terms leads to two kinds of approaches, the one deterministic and the other stochastic.

The deterministic approach is based on the assumption that when the numbers of susceptible and infected persons are known, together with rates such as those of attack, birth, and death, any future state of the host population can be precisely determined. From the stochastic point of view, the variables are regarded as probabilities; Bartlett's formulation, for example, is based on the assumption that infection and removal of susceptibles are random events in time, and he developed the probability generating

functions for these two variables—the numbers of susceptible and infected persons.

From another point of view, mathematical models are of two kinds, the point-infection type and the continuous infection type. The earlier models, including the Ross malaria equations, and the binomial expansions of Reed and Frost, of Soper, and of Greenwood, are of the point-infection type in that the period of infectiousness is contracted to a point, and the development of successive stages, or generations, of cases of disease following the introduction of infection into a susceptible population is described by the successive terms of a binomial expansion.1 More than one probability value may be functional in a given epidemic by inhomogeneity of mixing, e.g., that within families of various sizes and within the population as a whole, leading to binomial chains, and a stochastic element is introduced when the frequency distribution of these probabilities is taken into consideration.

The constant infection model of Kermack and McKendrick^{21, 28} may be illustrated in deterministic form, *i.e.*, by using constant infection and removal rates. In a homogeneously mixing group of n individuals, at time t there are x susceptibles, y infectious individuals, and z who are isolated, dead, or recovered and immune; then:

$$x + y + z = n$$

If a constant infection rate is designated β , and a constant removal rate γ , the number of infections in time dt is $\beta xydt$, and the number of removals is γydt , and the course of the epidemic is represented by the differential equations

$$dx/dt = -\beta xy$$

$$dy/dt = \beta xy - \gamma y$$

$$dz/dt = \gamma y$$

Approximate solution gives the rate of change of the total number of cases, or the epidemic curve, as

$$dz/dt = (\gamma^3 u^2/2\beta^2 x) \operatorname{sech}^2 (1/2u\gamma t - \theta)$$

and the total size of a small epidemic is approximately

$$(2\gamma/\beta x_0)(x_0-\gamma/\beta).$$

When t = 0 and the entire population consists of susceptibles, *i.e.*, x = n, unless $n > \gamma/\beta$, no epidemic can start, and the

relative removal rate, $\rho = \gamma/\beta$, gives the threshold density of susceptibles. When n is greater than the threshold density, e.g., $n = \rho + \nu$, the total size of an epidemic will be 2ν , reducing the initial density of susceptibles, $\rho + \nu$, to $\rho - \nu$, a value as far below the threshold ρ as it was above it initially. This is the Kermack and McKendrick Threshold Theorem and is illustrated in the accompanying figure.

When the continuous infection type of model is treated stochastically it becomes much more complex mathematically and will not be described here, but there is reason to believe that the stochastic model is a powerful tool in the study of the dissemination of infection. The development of such models serves to introduce an element of precision into epidemiological thinking, and their application has indicated their general validity. 4, 8, 17, 50 In any case, it is clear that the spread of disease and the generation of epidemics may be accounted for by application of the principle of mass action without recourse to unfounded assumptions of systematic variation in the virulence of the microorganism.

Herd immunity. The nature of herd immunity will become clear at this point, for the higher the proportion of immunes

in a population the smaller the probability of effective contact between case and susceptible; i.e., many of the contacts will be with immunes, and the population exhibits a group resistance to epidemic disease which may be of such a high order that an epidemic is no longer possible and the disease smolders in an endemic form as a result of the importation of new cases or the persistence of infection in healthy carriers whose contacts will give rise to an occasional case. A susceptible member of such an immune population, then, enjoys an immunity that is not of his own making but arises as a result of his membership in the group.

During the course of an epidemic, the decline in number of susceptibles to the threshold density coincides with the peak of the epidemic wave, and the incidence of new cases declines because the disease cannot reproduce itself. The total number of cases in the epidemic will, as described above, be twice the number of susceptibles in excess of this threshold density present at the beginning, and following subsidence of the wave the population is left with a greater or lesser degree of herd immunity.

Such precise relationships are only approximated in nature. In practice the thres-

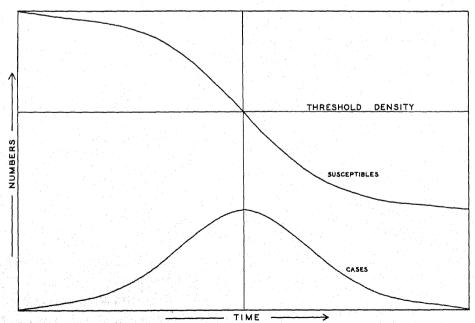

Figure 62. Diagrammatic representation of the course of an epidemic wave in terms of number of cases (lower curve) and number of susceptibles (upper curve). Note the coincidence of the peak of the epidemic wave with the threshold density of susceptibles. (After McKendrick.)

hold density fluctuates and is a function in part of dosage. For example, immunization of 30 per cent of preschool children suffices to control epidemic diphtheria, but the proportion is much higher in schoolchildren and 70 per cent is the commonly accepted level of herd immunity required to control epidemic diphtheria. The higher proportion required in older children is perhaps a consequence in large part of increased exposure to infection. Similarly, Sabin has estimated that immunization of 70 per cent of children should suffice to eliminate epidemic poliomyelitis.

When the prevalence of a disease is high. a given individual will be subjected to a greater number of bacteria per unit time; some, previously immune to smaller doses. will become susceptibles under such circumstances and the "effective concentration," so to speak, of immunes declines with consequent effect on the herd immunity to epidemic disease. This effect of dosage on the host population has been termed infection pressure and is a matter of considerable practical importance. This, in effect, alters the infection rate β , taken above as invariant, since it is related to dose per unit time, and alters ρ , the threshold density. Successive epidemic waves may, then, occur as a consequence of increased infection pressure as well as through the accumulation of new susceptibles (see below). Recurrent waves of a disease that is a clinical but not an etiological entity are, of course, another matter.

Long-term relationship. The question of the relationship between an infectious disease and a susceptible population over a long time is somewhat more complex. Mathematical treatment such as the Ross malaria equations and Martini's equations for immunizing diseases26 is too far removed from reality to have much practical significance, principally because the mathematical approach requires that the parameters remain constant over long periods. This condition is probably rarely if ever satisfied; it is well known, for example, that within the last century both diphtheria and scarlet fever, previously of low prevalence, took on a malignant character and higher prevalence for some decades and then within the last 50 years have gradually declined in both prevalence and severity. It is of some interest, however, that the differential equations of Martini, for example, show one stable equilibrium at the origin and another at a positive value which is approached by a series of oscillations above and below the final state of equilibrium so that a series of epidemic waves appears. These solutions suggest that (a) under certain circumstances a disease may tend to die out and (b) under other circumstances a disease will reach an equilibrium after a series of epidemics of decreasing severity. Such periodicity in the incidence of many infectious diseases is well known; one of the best examples is that of measles, which recurs in epidemic form at approximately two-year intervals. So far as is known, however, no infectious disease occurring under natural conditions shows a damped periapproaching invariancy though odicity it has been found to occur in experimental epidemics in which the immigration rate of the new susceptibles is very high.

A disease will, of course, die out if it does not reproduce itself, i.e., if the bacterium is present only in the active case and each case does not, on the average, give rise to a second case. It is not unlikely that some diseases are dying out in this way. It has been suggested, for example, that the decline in tuberculosis is due in part to inability of the disease to reproduce itself, a process accelerated by isolation of active cases. The second suggestion is of interest in connection with the epidemic periodicity of certain diseases such as measles. It is obvious, of course, that following an epidemic a new crop of susceptibles appears, and when their numbers reach a sufficiently high level, a new epidemic ensues, and so on ad infinitum. It is unlikely, however, that these epidemic waves are damped as predicted by theoretical equations, for subtle variation in the complex of factors that are oversimplified as parameters will wipe out the damping effect. It will probably be many years before predictions regarding the future of infectious diseases attain a status better than that of guesses.

EXPERIMENTAL EPIDEMIOLOGY^{16, 49, 51}

The information that may be derived from observation of naturally occurring disease, i.e., descriptive epidemiology, is limited since the observer has no control over the process, and for all practical purposes the experiment is carried out for, instead of by, him. In experimental epidemics, however, the conditions may be adjusted as desired, and it may be anticipated that such experiments will be highly informative.

The study of epidemics of infectious disease developed in populations of laboratory animals under controlled conditions has been carried out by Topley, Greenwood, Wilson, and others in England and by Webster and his colleagues in the United States. These experimental epidemiological studies have been confined, for the most part, to the study of the dissemination of Salmonella typhimurium (aertrycke), Sal. enteritidis, Pasteurella muriseptica, and the virus of ectromelia (mousepox) among populations of mice. Mouse typhoid and pasteurellosis are regarded as analogous to human diseases such as typhoid fever in which there is an imperfect immunity and carrier state, and ectromelia as analogous to human diseases in which a solid immunity is developed, such as diphtheria. The extent to which the analogies may be carried, and to which the conclusions reached are applicable to the considerably more complex human population as it exists under natural conditions, is open to some question; nevertheless, these studies, as yet in their infancy, have yielded valuable information.

The experiments which have been carried out were of two general types. The closed epidemic was produced in a population of mice, often about 50 in number, by the introduction of infected animals. The other type of experiment was carried out in an infected mouse population recruited by continuous immigration, *i.e.*, mice were added at regular intervals, the rate varying from one mouse every three days to six mice per day. The results may be summarized briefly:

(1) The epidemic wave initiated in the closed population by the introduction of infected individuals closely resembled those observed in the human population.

(2) The effects of dispersal of the infected population of the closed epidemic into large or small groups at various times during the development of the epidemic were studied. The time at which the population was dispersed was found to be of primary impor-

tance; the later the dispersal was effected, the less favorable the result, and after the peak of the epidemic wave was reached it continued unchecked even though the population was dispersed to individual mice. This is of particular interest since fleeing from an epidemic has been a popular method of escaping infection (cf. The Decameron). In this connection the results of dispersal of children from the industrial centers of England in 1939-1940 may be noted. A sharp reduction of 40 per cent or more in diphtheria morbidity occurred in the evacuated towns, together with an increase of 60 to 70 per cent among local children in reception centers, the latter returning to normal within six months. Similarly, the biennial periodicity of measles was broken by this dispersal.

(3) The effect of active immunization on the epidemic was not so great as might be supposed. If the mice were immunized prior to the epidemic, a favorable effect was apparent and more marked in ectromelia than in Sal. typhimurium infections. Immunization undertaken after the initiation of the epidemic was without effect.

(4) In the mouse population recruited by continuous immigration a series of epidemic waves developed, the frequency of which was directly related to the rate of immigration. Thus, with a low rate, such as one mouse every three days, epidemic waves were separated by periods of remission in which no deaths occurred. As the immigration rate was increased, the waves occurred with greater frequency, and with the addition of six mice per day there were no periods of complete remission, the epidemic waves taking the form of periods of increased mortality.

(5) With high immigration rates, the peaks and troughs in the daily death rate became less and less pronounced after a year or more, both the rate and total population tending to become invariant. Thus it was possible to approximate experimentally the damped periodicity and eventual equilibrium predicted on theoretical mathematical grounds (see above), and the experimental host population could be brought into approximate equilibrium with the parasite population.

(6) An inadvertent experiment with a population recruited by a high rate of im-

migration proved to be of considerable interest. The mouse population had reached the equilibrium indicated above by summer. when there was a heat wave of unusual intensity in London. There were many nonspecific deaths (mice are highly susceptible to heat), followed by violently fluctuating specific mortality. In the course of time an equilibrium was again reached but at a considerably higher death rate and decreased numbers than formerly. The parasite was shown to be unaltered in virulence, and the immigrants had not, of course, had the heat experience. Hence the host-parasite relationship per se was altered by an environmental "catastrophe." The relationship of these observations to the long-term relation between the human population and infectious disease is of interest. If it be assumed that the day of the mouse is equivalent to 30 days in the life of man, over the four years taken by this experiment the following were observed: (a) a period of stability with low regular death rates and growing population (ca. 600 days) equivalent to a human experience of slightly less than 50 years—this is longer than the 25-year period ending about 1830 during which the death rate from scarlet fever was relatively low: (b) a period equivalent to 15 years of severe and repeated epidemic waves; and (c) a period equivalent to some 30 years of relatively high mortality in a more or less stable state of equilibrium in a population reduced in numbers—the post-1830 epoch of virulent scarlet fever lasted more than 40 years.

(7) The mortality rates of the mice were intimately related to the length of time that they were members of the infected population; the rate rose rapidly to a peak in the early days of cage age and, although it declined slowly with the passage of time, to a greater extent in ectromelia than in mouse typhoid or pasteurellosis, the survivors of one epidemic wave may be the victims of another. The removal at regular intervals of a number of mice equal to the number added at the same intervals markedly altered the trend of these mortality rates: under these circumstances, the initial peak of mortality was lower, but the rapid decline was not apparent and the mortality rate remained at a high level. Removal was of considerable advantage to the individual mouse; in general, the earlier the removal the greater the advantage, except during the decline of an epidemic wave, when isolation did not increase the chances for survival of individual animals.

Although the evolution of the single epidemic wave in the experimental studies closely resembles its counterpart in the human population, the inability to control experimental epidemics by immunization is at variance with observations on epidemic disease in human populations. Some human diseases, such as diphtheria and smallpox, can be restrained from assuming epidemic proportions by active immunization of a sufficiently large number of the individuals making up the population. Whether or not this and certain other minor discrepancies prove to be real or illusory with future work. a number of pertinent suggestions have come out of these investigations. The response of the experimental host population in terms of mortality rates and cage life expectation cannot be interpreted as vet in some cases: in others the interpretation is questionable.

Some of the experiments, however, have yielded clear-cut results that bear directly upon the interaction of host and parasite populations in nature. Perhaps the most important of these is the experimental demonstration of recurring epidemic waves resulting from the continuous addition of new susceptibles to the infected population. In spite of the fact that such a sequence of events is predicted by theoretical epidemiology, as indicated above, the repeated flaring up of a disease of man or domestic animals, thought to be stamped out in the interepidemic periods, is most often taken as evidence of the re-importation of infection. The experimental demonstration of this phenomenon and the indicated futility of quarantine in the control of a disease which has become widely disseminated (only when a disease is not present, or present in limited effective foci, can quarantine and isolation procedures be effective) are, clearly, of considerable significance.

EPIDEMIOLOGICAL DATA AND THEIR INTERPRETATION²⁷

The purposes of epidemiological study are three-fold: first, to indicate the nature of the infective agent, its source, and modes of transmission when these are not fully established otherwise, *i.e.*, on an experimental basis; second, to extend this information into a corresponding general theory of the epidemiology of the disease; and third, to determine in detail the local conditions which favor or control the dissemination of the infection in a given area or community. For these purposes four general types of information, usually simple in character but wide in extent, are required.

Geographical distribution. The area in which the disease occurs and the regularity of its geographical distribution are highly informative. Thus, the general occurrence of a disease indicates that environmental conditions, including fauna, climate, etc., peculiar only to parts of the area are not essential to its transmission. Similarly, restriction of the disease within geographical limits indicates that special environmental conditions are necessary for its dissemination; these may include crowding, presence of an insect vector, water supplies, proximity to reservoirs of infection, etc. In general, a uniform distribution of the disease is indicative of a simple method of transmission, as in the case of measles, whereas an irregular distribution, such as that of spotted fever, implies a more complex process dependent upon a source of infection or conditions necessary to transmission that are correspondingly irregularly distributed.

Prevalence of disease. The prevalence of the disease suggests the source of infection. A high rate, such as that of measles, indicates that the observed cases are the most important, if not the only, source of infection. Conversely, sporadic distribution of widely separated cases implies the existence of a concealed reservoir of infection such as the casual or chronic carrier or some of the lower animals.

Seasonal distribution. The seasonal distribution is also informative when considered together with other epidemiological features of the disease. Thus, a seasonal occurrence may be consistent with hypothesized insect transmission, or it may eliminate an insect vector as the sole transmitting agent.

Age distribution. The age distribution of the disease is suggestive as a corollary to other epidemiological characteristics, and often aids in their interpretation. Thus, a disease occurring for the most part in the

early years of life, such as measles or diphtheria, often shows differences in age incidence between urban and rural areas which are explained by the more frequent occurrence of immunizing infections, apparent or subclinical, in the more crowded areas. Since similar differentials are apparent in poliomyelitis, the age distribution of this disease, together with other of its epidemiological features, supports the view that this disease is widely prevalent as a subclinical infection.

Epidemiological evidence, therefore, consists of a series of interrelated facts from which a conclusion or series of conclusions may be drawn. The first step in epidemiological procedure is necessarily the demonstration of associations between the frequency of occurrence of the disease and some conditions or set of conditions; the second, the ascertaining of the relationship of these associations with one another; and third, their relations to the general epidemiological theory of the disease. To take a simple example, in milkborne typhoid fever it may be ascertained that cases of the disease occur predominantly along the route of the milkman, that in families so supplied the cases occur among those who drink milk, that the cases appear within a limited time to suggest simultaneous infection, and that an employee of the dairy is a carrier of typhoid bacilli. Not only are these associations related to one another but they are consistent with the general epidemiological theory of typhoid fever, viz., that transmission is basically a matter of the transfer of infected fecal material (or urine) from a patient or carrier to the mouth of a susceptible person.

While this would appear self-evident, there is an opinion of some prevalence that, since epidemiological evidence is necessarily purely circumstantial, it cannot be conclusive. This is perhaps due in large part to failure to appreciate the development, often basically statistical and therefore mathematical, of the logical analysis, and the significance of the body of evidence as a whole. The method of analysis and interpretation of epidemiological evidence is identical with that of experimental evidence, the practical difference lying in the fact that, as pointed out earlier, the epidemic is an experiment done for, rather than by, the observer and cannot be manipulated.

THE CONTROL OF INFECTIOUS DISEASE^{2, 35, 54}

With an understanding, albeit admittedly imperfect, of the factors which determine the means and extent of the dissemination of infectious disease, comes the possibility of control. The variety of epidemiological types of disease and the individual variability within these broad groups make for differences in control measures, and the control of a given disease under given circumstances almost always constitutes a special case. In general, however, control measures are of three kinds, *viz.*:

- (1) Those directed toward reduction or elimination of the source of infection, such as
 - (a) Quarantine and isolation of cases and carriers
 - (b) Destruction of an animal reservoir of infection(c) Treatment of sewage to reduce water contamination
 - (d) Therapy that reduces or eliminates infectivity of the individual
- (2) Those designed to break the connection between the source of infection and susceptible persons, *i.e.*, general sanitation measures such as

(a) Chlorination of water supplies

(b) Pasteurization of milk

- (c) Supervision and inspection of foods and food handlers
- (d) Destruction of insect vectors
- (3) Those that eliminate the susceptible and raise the general level of herd immunity by immunization, including

 (a) Passive immunization to give a temporary immunity following exposure or when a disease threatens to take epidemic form

(h) Active immunization to protect the individual from disease and the host population from epidemic disease.

One or another, or a combination of, such control measures are applicable to most infectious diseases of man and may be illustrated for the major epidemiological types of disease.

Diseases of lower animals transmissible to man.⁴³ Diseases in this group have in common an animal reservoir of infection. Direct control of the source of infection is, therefore, sometimes possible. When the transmission is direct, as in rabies, the reservoir of infection in the domestic dog may be controlled by immunization and quarantine of animals. The reservoir in wild animals, however, is not subject to such control, and complete elimination of the disease cannot be accomplished except locally under exceptionally favorable circumstances. The animal reservoir of bovine

tuberculosis is, of course, subject to direct control and may be, and has been in this country, eliminated by slaughter of infected animals. Here the pasteurization of milk also provides protection to the human population.

Insectborne diseases. Control of diseases transmitted by insect vectors is often most readily approached through control of the vector. Thus malaria control is, for all practical purposes, mosquito control, and louseborne typhus may be controlled by measures directed against the human body louse as well as by immunization of man. In instances such as these the vector is closely tied to man, by preference or by necessity, but when a disease has a reservoir of infection in wild animals and is transmitted by a vector that bites both those animals and man, control is more difficult. Plague is an example of an intermediate disease in this respect. The rat reservoir of infection is closely associated with man. and both the rat and rat flea populations are subject to an effective degree of control. but neither the wild rodent reservoir nor the insect vectors of sylvatic plague are subject to any appreciable degree of control. Similarly, tularemia and spotted fever, the latter having a reservoir in the tick, cannot be effectively controlled.

Diseases transmitted from man to man. Control of the source of infection in these diseases is a matter of quarantine and isolation, and in some instances the continued application of these may tend to eliminate the source. Thus, it is possible that human tuberculosis may eventually be practically eliminated in this country by isolation of cases; for many years the disease has not been reproducing itself, and the incidence shows a steady decline. Isolation is not, however, applicable to those diseases in which the reservoir of infection is the asymptomatic casual carrier, such as diphtheria. The diseases that are largely transmitted indirectly by water, food, milk, etc., are controlled with relative facility by general sanitation practices such as chlorination of water supplies and pasteurization of milk. In some cases these control measures also eliminate or reduce the reservoir of infection in a given area. Cholera, for example, has for many years been nonexistent in this country and western Europe. Typhoid fever is a more difficult matter because of the chronic carrier state, but when it is adequately controlled, the carrier incidence declines, thus reducing the reservoir of infection. As yet, airborne infection cannot be controlled so far as transmission is concerned.^{23, 24, 25}

When immunization is effective, these strictly human diseases can be controlled by its mass application, but mass immunization is weighed against other methods of control in terms of practicality. While, for example, a reasonable degree of immunity against typhoid fever may be obtained, chlorination of water supplies is a much more practical method of control of this disease than mass immunization under ordinary conditions in this country. In other diseases, however, such as diphtheria and small pox, mass immunization is by far the most practical method of control.

Chapter Eleven

THE MICROBIOLOGY OF WATER AND SEWAGE

Of the interrelationships between the members of human populations that facilitate the transmission of infection, those arising as a consequence of common water supplies and the group disposal of sewage are among the most important. Transmission of disease by this means is confined to diseases of the so-called enteric group, in which infection takes place via the gastrointestinal tract and the causative microorganisms are discharged with the feces: Infection is, therefore, the result of a direct connection between infectious fecal material and the mouth of a susceptible person, and when that connecting link is a common water supply, as it frequently is, outbreaks of cholera, typhoid fever, and the like occur. This link is, however, readily broken; the great waterborne epidemics are rapidly becoming a thing of the past as a consequence of the utilization of effective control measures, and present-day waterborne epidemics are indicative, not of a lack but of a failure to make use of existing knowledge.

WATER11, 24, 26

Because of waterborne disease and the obvious desirability of its control, studies of the bacteriology of water have been directed, for the most part, toward its sanitary aspects. The best single criterion by which the sanitary quality of a water may be judged is, clearly, the kind and numbers of bacteria that are present in it. If it were possible, as a routine procedure, invariably to detect the presence of the appropriate disease-producing bacteria, it would be unnecessary, from

the sanitary point of view, to take the non-pathogenic forms into consideration. This is, however, not the case; a judgment of the sanitary quality of a water cannot be made on the basis of failure to find a microorganism such as the typhoid bacillus in that water. This bacterium, for example, is usually so outnumbered by similar forms such as the colon bacillus that its isolation and identification require enrichment cultures in selective mediums and other time-consuming procedures; even then these are not always successful, and a negative finding is of doubtful value.

It is legitimate to assume, however, that when a water is polluted with human fecal material, it is probable that it contains bacteria which cause enteric infection. This probability becomes a certainty when the fecal material is pooled, as in the sewage of a community, because of the ubiquitous presence of healthy carriers of typhoid bacilli and similar microorganisms. Since it is impractical to isolate these pathogenic bacteria themselves as a routine measure. some indicator of fecal pollution will serve equally well as a criterion of the sanitary quality of a water. The question, which was stated many years ago, becomes this: Are there types of bacteria which are never present in natural waters free of pathogenic bacteria but which may always be found in water polluted with human fecal material and therefore probably with pathogenic bacteria? If so, such types of bacteria can be used as indicators of pollution. The answer to this question involves a consideration of the bacterial flora of natural waters, including both bacteria which are native inhabitants of water and those microorganisms whose presence is a consequence of contamination from external sources.

Bacteria native to natural waters. The bacteria whose native habitat is water are not well known, in part because many of them are difficult to grow on laboratory mediums. There is no question, however, of the existence of a bacterial flora normal to and characteristic of natural waters. The types of bacteria which make up this natural population may be considered briefly:

- Higher bacteria, frequently the sheathed forms assigned to the Chlamydobacteriales and including sulfur, iron, and other forms
- (2) The Caulobacteria, a group of "stem" bacteria which occur in lakes and other bodies of water attached to some inanimate object
- (3) The spiral forms, which are frequently found in great numbers in water, some of which may be very large, 20 to 30 μ in length, as compared with the parasitic spirilla
- (4) A variety of bacilli, including
 - (a) Pigmented forms such as Serratia marcescens, Chromobacter violaceum, and Bact. aurescens
 - (b) Various nonpigmented forms such as:
 - 1. The fluorescent bacteria Pseudomonas fluorescens
 - 2. Certain of the sulfur bacteria
 - 3. Thermophiles
 - 4. Aerobic, spore-forming bacilli of uncertain taxonomic position
- (5) Coccus forms, both
 - (a) Pigmented, generally yellow—very often Sarcina lutea, and
 - (b) Nonpigmented-Micrococcus aquatilis, M. candicans, and others
- (6) Nitrogen-fixing bacteria—Azotobacter aquatile in particular
- (7) Nitrifying bacteria both Nitrosomonas and Nitrobacteria

These water bacteria are found in fresh water in swamps, streams, and lakes: The bacterial populations of salt waters have not been studied as extensively, but it appears⁴⁰ that the sea contains similar bacteria, including the nitrogen-fixing forms, the fluorescent bacteria, various pigmented forms, and the like. The water bacteria bear the same relation to the constant and recurring transformations of organic matter that take place in natural waters as they do to the same processes in the soil and are, therefore, an integral part of aquatic life. ¹⁰

Some, but by no means all, of the water bacteria can be cultivated on laboratory mediums. In any case no one medium suffices; the nitrifying bacteria, for example, cannot be grown in the presence of organic matter. Since the bacteria found on plates are of necessity only those that will grow upon the medium used, it will be clear that the value of plate counts as estimates of the numbers of these microorganisms is questionable. Enrichment cultures are sometimes useful, and it may be noted parenthetically that the simple holding of a water sample for a period of hours will frequently result in a marked increase in numbers. Considerable information has been obtained by a method of "slide culture" in which a clean glass slide is suspended in the water for several days, removed, stained, and studied microscopically.

Bacterial contamination of natural waters. In addition to the native water bacteria, a given water may, and usually does, contain a variety of bacteria as contamination from external sources. These sources are two—the air and soil, and human and animal excreta.

Bacteria from the air and soil. The number of bacteria in the air bears, as might be supposed, a close relation to the quantity of larger suspended particles or "dust." There are fewer bacteria in the air of the country than of the city, fewer in mountain air than in the air of the lowlands, and the air in mid-ocean is nearly bacteria-free. Under appropriate circumstances bacteria suspended in the air are those expelled from the upper respiratory tract of human beings and are of no small significance in the transmission of "droplet infection," but insofar as air in general is concerned this is an insignificant and relatively rare occurrence. Pathogenic microorganisms, such as the tubercle bacillus and the pyogenic cocci, have been found in the air of hospitals and sickrooms, but as a rule pathogenic bacteria in dry dust are exceedingly rare. The kinds of microorganisms in the air vary somewhat in different localities, but certain forms are generally present. Molds and yeasts are quite common and in some instances outnumber the bacteria. These include various species of molds such as Penicillium glaucum (the blue-green mold) and various yeasts, many of them the pigmented (red) torulae. Bacillus subtilis and related forms, together with the various micrococci, often pigmented, are almost universally present.9 They find their way into natural waters through settling out or are swept down by

Many of the bacteria present in the air, particularly the aerobic spore-formers, are essentially soil forms blown up in dust and able to survive drying. The soil itself contains tremendous numbers of bacteria; a gram of average field soil probably contains 100 million to 50 billion living bacteria, most of which are found in the upper 6 inches of soil, few being found in undisturbed soil below a depth of 4 to 5 feet. The great majority of these microorganisms are native to the soil and include the nitrogen-fixing and nitrifying bacteria, bacteria of the amylobacter group, and a variety of forms whose biochemical activities are an integral part of the mechanism of the decomposition of organic matter in the soil. A small part of the native bacterial flora of the soil consists of potential pathogens such as Clostridium tetani, Cl. edematis, and Cl. botulinium.

Bacteria other than those which make up the normal flora of the soil may be present as contamination. For practical purposes the pathogens that may be present may be regarded as coming from one of two sources: the flesh of animals and of persons who have died of infectious disease, and the excreta of human beings. In the first instance only one organism, the anthrax bacillus, is of significance, for other bacteria causing diseases of animals and man, such as the causative agents of tularemia, plague, spotted fever, and other diseases of animals, together with the bacteria of human disease such as the diphtheria bacillus and streptococci, do not survive long in the soil.

In the case of the anthrax bacillus, however, the spores are able to survive for long periods, perhaps years, and are brought to the surface from buried bodies by earthworms. Pastures may, then, remain infective for cattle for a long time.

The pathogenic bacteria contained in human excreta are those microorganisms which leave the body via the intestinal tract, *i.e.*, those causing the enteric diseases. The bacteria do not multiply in the soil, but their vitality may be considerably prolonged, possibly for two or three months.

It will be clear that microorganisms present in the air and in the soil have relatively ready access to bodies of water, and contamination may take place either more or less continuously or at irregular intervals under certain unusual conditions, as during and immediately after heavy rains. The contribution of air and soil, the latter in particular, to the bacterial flora of water is, then, considerable. Some of the potential pathogens, e.g., the bacilli of tetanus and malignant edema, are not infective when taken by mouth, and others, even though they survive for sufficient periods, rarely produce infection by this route. The normal portal of entry of the enteric bacteria is, however, the gastrointestinal tract, and it is these microorganisms which constitute the significant contribution of contamination through the agency of soil.

The intestinal microorganisms may be washed directly into lakes and rivers or other bodies of water by heavy rains; hence the presence of excreta on water sheds and consequent contamination of impounded waters is of considerable practical importance. In many instances, particularly in the case of shallow wells and the like, typhoid and other bacilli enter the water supply from privies, latrines, and similar devices via ground water. The distance over which such contamination can travel is a function of the rate of death of the bacteria and the rate of ground water flow. The latter is obviously dependent upon many factors such as the amount of rainfall, the local geological formations, and the like, and each instance of contamination, or possible contamination, must be considered individually. In general, fine soils and sand tend to impede their progress to a greater extent than coarse sand and gravel. The rock formations are of considerable significance; sandstone, for example, filters out bacteria, while limestone tends to erode with the formation of direct communicating channels, and wells drilled into such formations may contain typhoid bacilli which entered the water many miles away and are, therefore, always to be regarded as dangerous. The rapid spread of suburban living, often beyond municipal water supply and sewage disposal systems, has resulted in a revival of the problems of ground water contamination37 formerly confined to rural areas.

Contamination by excreta. Contamination of water by human excreta may take place, not only indirectly through the agency of soil as noted above, but also directly. Such direct contamination is, for the most part, a consequence of human population densities and urban organization and takes the form of dumping of sewage of one com-

munity into a body of water which serves as a water supply to another. Whether directly or indirectly contaminated, such waters contain not only the native bacterial flora supplemented by microorganisms from the soil, but also the flora of the human intestine. The contribution of the last consists of very large numbers of coliform bacilli. and much smaller numbers of Cl. welchii, the α -hemolytic fecal streptococci or enterococci (Streptococcus fecalis), together with whatever pathogens may be present. The pathogenic microorganisms are the pathogenic enteric bacteria such as the typhoid and paratyphoid (Salmonella); dysentery bacilli; where the disease is endemic epidemic, the cholera vibrio; certain of the animal parasites such as pathogenic amebae and Ascaris; and the so-called enteric viruses present in the bowel and excreted in the feces such as the polio and Coxsackie viruses and those of the ECHO group.

Under some conditions contamination by animal excreta assumes some importance. For example, surface water may contain coliform bacteria from domestic animals, and the presence of these does not carry the same implication as that of coliform bacteria of human origin. In other instances animal excreta may contain bacteria pathogenic for man, *viz.*, the contamination of water with leptospira from rat urine. Usually, however, contamination with animal excreta is not of great sanitary significance.

factors influencing the kinds and numbers of bacteria. The numbers of bacteria that may be found in a given water are dependent primarily upon the type of water, whether it is a surface water, such as that found in streams, lakes, and shallow wells, or a deep water from deep driven wells. In the first instance opportunities for contamination are great and, as might be expected, many bacteria are present. The water from deep wells, on the other hand, has undergone effective filtration in order to reach the deeper strata in which it is obviously not subject to any extensive contamination; hence relatively few bacteria are found.

A variety of environmental factors influences the bacterial content of water; chief among these are the amount of organic matter present and the temperature. In general, the more nutriment there is present in the form of organic matter, the greater is the number of bacteria. Low temperatures are not conducive to rapid growth and tend to keep the numbers of bacteria down, a factor that favors the survival of pathogens such as the typhoid bacillus which are unable to multiply in any case. Higher temperatures result in an increase in bacterial numbers in the presence of sufficient organic matter, but if the supply of nutriment is not great, after a preliminary increase during which the food supply is exhausted, the numbers fall below the initial level. Other environmental factors are not infrequently influential in determining the types of bacteria present in a water; thermophiles will, of course, predominate in hot springs and sulfur bacteria in sulfur springs, and the acidity of many natural waters results in a limited flora of acid-resistant bacteria.

Bacteria in ice. Although it is difficult if not impossible to sterilize a substance by exposure to low temperatures, many of the bacteria present are killed, only the resistant cells surviving. The great majority of bacteria in water are killed by freezing. Hence ice always contains but a fraction of the number in the water from which it was formed. Over 90 per cent both of the ordinary water bacteria and of typhoid bacilli die within a few hours, and a progressive decline in numbers then takes place, less than 1 per cent of typhoid bacilli surviving at the end of a week of freezing. Ice stored for six months is practically sterile. Outbreaks of typhoid fever have rarely been traced to the use of ice, although in a few instances the evidence of ice transmission seems quite conclusive. Danger of typhoid infection from the use of ice in drinking water is, in the absence of direct contamination of the ice during handling, always less than from the use of water from the same source as the ice.

The bacteriological analysis of water.^{1, 23} It will be apparent from the above discussion that the bacteria whose presence in water is a consequence of fecal pollution are not present in uncontaminated water and are sufficiently different from the native water bacteria that they may be readily distinguished. Of these bacteria the coliform bacilli are present in greatest numbers, while Str. fecalis and Cl. welchii, although constantly present, are usually not so numerous. It would appear, therefore, that any of these microorganisms could be used as an indicator of pollution. The coliform bacilli are

used almost exclusively in this country, and both *Str. fecalis* and *Cl. welchii* have been used in Europe. The streptococci are, however, sometimes difficult to differentiate and die out more rapidly than coliform bacteria. *Cl. welchii* has the disadvantage that its spores remain viable over long periods in contrast to coliform bacilli which, although more hardy than the typhoid bacillus, die out in time; hence *Cl. welchii* does not allow the differentiation of recent and old pollution.

The bacteriological examination of water for the presence of coliform bacilli rests upon the fact that this microorganism ferments lactose. The standard procedure for the examination has been prepared jointly by the American Public Health Association and the American Water Works Association and is revised at frequent intervals. Briefly, it consists of three parts: (1) the presumptive test, (2) the confirmed test, and (3) the completed test. In the first, lactose broth is inoculated with decimal dilutions of the water sample, commonly 10 ml., 1 ml., and 0.1 ml. (expressed as dilutions these are, respectively, 0.1, 1, and 10). The volume of the smallest inoculum producing fermentation provides a crude approximation of the numbers of coliform bacilli present in the water. Of the selective enrichment mediums containing ox bile and/or brilliant green or ricinoleate or lauryl sulfate, only lauryl sulfate tryptose broth has been officially accepted for the presumptive test without confirmation, and then not for filtered or treated waters. A more accurate estimate may be obtained by inoculating five tubes with each dilution and calculating the most probable number of coliform bacilli on the basis of the number of tubes in which fermentation occurs.30,36 Tables for calculation of the most probable numbers (MPN) are given by Prescott, Winslow, and McCrady.26 The confirmed test consists of the inoculation of a specified selective medium such as Endo or eosin-methylene blue (EMB) plates, brilliant green lactose bile broth, crystal violet lactose broth, fuchsin lactose broth, or formate ricinoleate broth. The appearance of typical coli colonies on the plates or fermentation in the selective lactose broth constitutes a positive confirmed test. In the completed test one or more typical colonies are picked from an Endo or EMB plate inoculated either from the original lactose broth culture or from the secondary selective medium showing fermentation and are transferred to an agar slant and a lactose fermentation tube. After incubation the slant culture is smeared and stained and examined for the gram-negative nonspore-forming rods of coliform bacilli. If the culture is found to be morphologically coliform bacilli and the lactose is fermented, the completed test is positive.

Membrane filter procedure.⁵ This method of enumerating bacteria in water, and in other fluids for special purposes such as quantitative blood culture, was introduced by Goetz in Germany in 1947 and subsequently was widely studied in this country. The microbial indicator is usually coliform bacilli, but enterococci may be enumerated also.²⁸

It consists essentially of the filtration of the water sample by negative pressure through a cellulose disc which will retain the bacteria,* removal of the filter disc to an absorbent pad† containing a differential liquid medium such as Endo medium in the case of coliform bacilli, and incubation. The bacterial colonies grow upon the surface of the filter disc and may be counted.

Duplicate 100 to 500 ml. volumes of finished, i.e., regarded as potable, water, single filtrations of each of 0.1, 1, and 10 ml. volumes of well water, and appropriately reduced amounts of polluted waters are examined. The volume to be filtered is not less than 20 ml., and when the sample is smaller than this it must be diluted to 30 ml. with sterile buffered water. The filter disc, sterilized in the autoclave prior to use, is removed after filtration and rolled, avoiding the entrapment of air bubbles, onto the absorbent pad containing nutrient medium in a sterile petri dish. The membrane is incubated for two hours and then transferred to a fresh pad saturated with the nutrient medium, and incubated overnight. The colonies are then counted.

The coliform counts so obtained are somewhat lower than those estimated by the MPN method. Whether the two methods do not measure precisely the same microorganisms, or whether the difference is a

^{*}Such as the Millipore type HA grid marked filters or their equivalent.

[†]Equivalent to Schleicher and Schuell No. 470 filter paper, approximately 48 mm. in diameter and capable of absorbing 1.8 to 2.2 ml. of nutrient medium.

result of the mathematical bias³³ of the MPN method, which is reported to give estimates 20 to 25 per cent higher than the actual coliform density, is not yet clear.

This is the direct membrane filter test. When the completed test procedures described above, *i.e.*, representative colonies, are examined further and shown to be nonspore-forming gram-negative bacilli which produce gas in lactose fermentation tubes, the test becomes the verified membrane filter test.

The microbial indicator. It is self-evident that a satisfactory indicator of pollution must persist at least as long as, and preferably longer than, the pathogenic microorganisms that may accompany it. The microorganisms used, coliform bacilli, enterococci, and Cl. welchii, all persist longer than the pathogenic enteric bacilli, such as the typhoid bacillus, and the first may under some circumstances show a transitory multiplication. The survival of enteric viruses is similar to that of pathogenic bacteria, but at least some of them, such as Coxsackie viruses, may persist longer than coliform bacilli at low temperatures, 8° to 10° C.,8 and these and other viruses such as poliovirus are more resistant to chlorination than coliform bacilli. In the case of treated waters, then, coliform counts may be reduced to "acceptable" levels even though some of the enteric viruses may persist. The matter of viral contamination of potable water has not yet been satisfactorily settled.

The casual and inclusive term coliform bacilli has been used advisedly above. The group is a heterogeneous one within the larger group of gram-negative enteric bacilli (Chap. Nineteen). Those which ferment lactose promptly are the microorganisms found in the foregoing tests for fecal pollution and include the coli and aerogenes types together with forms intermediate between them. These are placed in different genera, e.g., Escherichia coli and Aerobacter aerogenes in this country, and in the genus Bacterium elsewhere, and it is becoming apparent that A. aerogenes as currently defined is contracting, the great majority of these forms becoming A. cloacae or Cloaca cloacae, depending upon the nomenclature followed.

Aside from matters of nomenclature, differentiation of these coliforms from one

another is readily accomplished by biochemical reactions which are standardized for this purpose (Chap. Twenty). Whether such differentiation has any significance with respect to the sanitary quality of a water is another matter. It has been felt by some that the coli type is to be associated primarily with fecal contamination, while the aerogenes type may occur free in nature and that the latter has less sanitary significance. However, the aerogenes type also occurs in the bowel and is seldom found in the complete absence of possible fecal contamination of soils, and it is doubtful that the differentiation of the two types has significance in other than exceptional conditions.

As indicated above, the α -hemolytic streptococci of fecal origin, the enterococci. and Cl. welchii tend to be of uniquely fecal origin, and have been used as indicators of pollution. The enterococci have been of interest in this country in connection with the microbiological assay of swimming pool waters (see below), though here also the coliform bacilli have been used most often. In general, a lack of suitable culture mediums for the detection and enumeration of enterococci has been a practical difficulty, and a number of reasonably satisfactory culture mediums have been developed.22, 29 Such mediums are made selective by the inclusion of sodium azide, and differential with certain dyes such as ethyl violet or triphenyl tetrazolium chloride, and the membrane filter method may be applied.²⁸ Enterococci tend to persist longer than pathogenic enteric bacteria, but not as long as coliforms, and are usually found in considerably smaller numbers than coliforms.

Plate counts. It is usually desirable to have an approximate measure of the total number of bacteria in drinking water, not because the sanitary quality of a water can be judged on this basis alone, but because such information frequently has ancillary value. The counts obtained by quantitative dilution and plating are, it must be remembered, those of the microorganisms that will grow on the medium used, other bacteria being quite inapparent by this method.

Two series of plates are poured, one in which the medium is nutrient gelatin and the other nutrient agar, or both may be nutrient agar. The gelatin plates, or one set

of agar plates, are incubated at 20° C. and the agar plates at 37° C. In general the native water and soil bacteria grow best at 20° C., in some cases they do not grow at all at 37° C., and bacteria of animal origin grow most rapidly at body temperature. The relative numbers of microorganisms growing at the two temperatures are, then, at times suggestive of the origin of the bacteria found.

Chemical analysis. The analysis for appropriate chemical compounds frequently is of value as an adjunct to bacteriological analysis in the determination of the sanitary quality of a water.1, 23 Pollution by sewage, for example, adds complex compounds protein, carbohydrate, and fat – to the water, and the amount and state of the decomposition products of these substances may serve as an index of the degree and time of pollution. Ammonia, nitrites, nitrates, chlorides, and albuminoid nitrogen are usually determined. Of these, chloride and, to a certain extent, nitrate, are the most useful. Chemical analysis of water is frequently made in connection with hardness, turbidity, taste, smell, and similar features, which, while often of considerable industrial or esthetic significance, are of no sanitary importance.

The assay of the sanitary quality of water.¹ The means by which the sanitary quality of a water is judged may be summarized briefly:

- (1) The bacteriological analysis, including both
 - (a) The presence or absence of coliform bacteria and
 - (b) The number and type of bacteria present
- (2) The type of water, whether surface or deep
- (3) The local conditions
- (4) Chemical analysis.

Of these the presence and numbers of coliform bacteria are the most important, and it must be remembered that the relative abundance, rather than the presence, of these microorganisms is the essential feature of the test. The discovery of a single colon bacillus in 50 ml. of water, or even occasionally in 5 ml., affords no reasonable ground for suspicion of the water. The possibility of sporadic contamination with colon bacilli derived not from man but from domestic animals or birds must be kept in mind. Manured fields and pastures, filled with grazing cattle or sheep, are likely sources of colon bacilli and may give rise to mistaken inferences if the environmental examination of a water supply is neglected. Knowledge of such local conditions as well as the type of water is, then, essential to the interpretation of the bacteriological findings. Chemical analysis may be of considerable help in some instances, but in general finds its greatest utility in the study and control of gross pollution in which the decomposition of organic matter and presence of industrial wastes are a nuisance, rather than the assay of the purely sanitary quality of a water.

Drinking waters. The question of the significance of the bacteriological findings brings up the matter of standards to which a water suitable for drinking should conform. Now it will be clear that, although considerable numbers of colon bacilli in a water are always suggestive of fecal contamination by man or animals, a standard is necessarily a minimum which is inherently difficult to define under the circumstances. In this country the United States Public Health Service has prepared recommended standards³⁴ which are intended to represent a minimum. In the recommended procedure the frequency of sampling is dependent upon local conditions, the minimum varying from one sampling per month for a population of 2500, to 500 per month for a population of five million. The sample is five 10 ml. portions, or five 100 ml. portions. The results of bacteriological examination by Standard Methods procedures should be as follows:

- Of all 10 ml. portions examined per month, not more than 10 per cent shall show the presence of coliform bacteria.
- (2) Occasionally more than three of the five samples show coliforms; this must not occur in more than 5 per cent of samples when 20 or more samples are taken per month, or in more than one sample if less than 20 samples are taken per month.
- (3) Should such a result (as in 2) be obtained from a single standard sample, daily testing must be carried out until at least two consecutive satisfactory samples have been found. Such daily samples are to be regarded as "special samples" and not included in the monthly totals.
- (4) With regard to the 100 ml. samples:
 - (a) Not more than 60 per cent shall show coliforms.
 - (b) Occasionally all five portions constituting a single sample will show coliforms; this must not occur in more than 20 per cent of samples when five or more samples are examined per month, or in more than one if less than five samples are taken per month. If so, daily "special samples" must be taken as above.

The water shall be satisfactory as to taste, odor, and color and shall contain less than the following minimum quantities of chemical impurities: lead, 0.1 ppm; fluo-

rine, 1.5 ppm; arsenic and selenium, 0.05 ppm; copper, 0.3 ppm; iron and manganese, 0.3 ppm; magnesium, 125 ppm; zinc, 15 ppm; chloride and sulfate, 250 ppm; total solids, 500 ppm; phenol, 0.001 ppm.

The British Ministry of Health suggests standards²³ based on the presumptive coliform count as determined by acid and gas formation in MacConkey broth on the piped supply entering the distribution system. Waters are divided into classes on the following basis:

Class I—Water of class I and regarded as highly satisfactory contains less than one coliform per 100 ml.

Class II—Water regarded as satisfactory contains one to two coliforms per 100 ml.

Class III—Water regarded as suspicious contains three to 10 coliforms per 100 ml.

Class IV—Water regarded as unsatisfactory contains more than 10 coliforms per 100 ml.

While a presumptive test alone is specified, the occurrence of positive presumptive tests has been found to be very high in Britain. Waters of classes I and II conform closely to the American standards.

The World Health Organization has compiled standards in the sense of bringing together common practices and criteria of water examination, together with suggested procedures;³⁸ in general these resemble closely those described above.

Swimming pools and bathing places.²¹ The sanitary control of water in swimming pools and bathing beaches is similarly based on bacteriological examination. The American Public Health Association has recommended that not more than 15 per cent of samples of swimming pool water contain more than 200 bacteria per milliliter or give positive confirmed tests for coliforms in any of five 10 ml. samples when the pool is in use. The standard is as high as that for drinking water, but pools are usually filled with water of drinking quality, and pollution is not only derived from bathers but is fresh and may be highly infective. The presence of acid-forming streptococci is also of considerable utility as a measure of oral and skin contamination, and usually corresponds closely to the total count. Staphylococci, present in the nose and throat and on the skin, would appear to be a logical indicator for swimming pool water, and their use has been proposed.6 It has been shown that the number of staphylococci is directly related to the bathing load, and being more resistant they persist longer than coliforms, so that relatively large numbers of staphylococci may be present in the virtual absence of coliforms.

Such waters commonly contain residual chlorine which must be neutralized with thiosulfate when samples are collected for bacteriological examination. In natural outdoor bathing places the test for coliforms is the most important. The standards are necessarily much more lenient than those for indoor pools, and those adopted locally vary from an allowable 100 coliforms per 100 ml. in California and Indiana to 3000 coliforms per 100 ml. allowed by the New York City Health Department.

Purification of water supplies. 13, 39 When, by bacteriological examination or otherwise, a water is known to be unsafe for consumption, the question arises as to ways and means of artificial purification. There are a number of useful methods of purifying water, differing according to the amount and character of the water to be treated, which may be summarized as follows:

- (1) Mechanical methods
 - (a) Storage
 - (b) Filtration
 - 1. Slow sand filtration
 - 2. Coagulation and rapid sand filtration
- (2) Chemical methods
 - (a) Large scale-hypochlorites and liquid chlorine
 - (b) Small scale—hypochlorite, ultraviolet light, ozone, etc.

Of these, storage is not generally regarded as a method of water purification, though the numbers of bacteria are usually greatly reduced in impounded waters because of the exhaustion of the food supply and the consequent death of bacteria and settling, not so much of bacteria alone as of suspended matter which carries down bacteria with it. The partial removal of suspended matter is frequently desirable, particularly with turbid waters, and may be carried out by allowing the water to remain in a settling basin for a time.

Slow sand filtration, one of the earliest and most effective methods of water purification, is in use in many European and some of the older American cities. These sand filters are constructed so that the water passes through 1 to 5 feet of sand supported upon graded layers of gravel. The rate of filtration must be accurately regulated and

the efficiency of operation controlled by frequent bacterial test of the effluent. Such filters are highly effective. Bacteria are removed, not to any great extent by mechanical straining out, but through a biological mechanism in which the activity of protozoa is an important feature. The passage of water through these filters is necessarily a relatively slow process and, in consequence, relatively large areas are required, which, for financial or other reasons, are no longer available in large American cities. Few of these filters have been constructed in recent years, and the use of rapid sand filters is becoming common.

The rapid sand filters, which may be used with turbid waters that would clog a slow sand filter, are frequently employed in conjunction with "coagulation," the addition of such substances as aluminum or ferric sulfate, which form flocculent precipitates (the hydroxides). The precipitate carries down most of the suspended matter and, of course, many bacteria, and is readily filtered out, yielding a clear effluent containing relatively few bacteria. Such filters must be cleaned from time to time, a process that is seldom required with slow sand filters. They make possible, however, the treatment of a large quantity of water on a relatively small filtering area.

Destruction of pathogenic bacteria in water supplies is most often brought about by treatment with germicidal chemicals. Of these, hypochlorite (calcium hypochlorite or bleaching powder) was at one time used widely in the treatment of municipal water supplies, and it still has its uses, although it has been largely superseded in large-scale treatment by liquid chlorine, which is supplied in cylinders under pressure. Chlorine is added directly to the water through an automatic feeding device in accurately measured amounts which are determined by the character of the water. In general, the greater the amount of extraneous organic matter present, the greater must be the amount of chlorine added.

The amount of chlorine taken up is termed the chlorine demand, and the point at which the residual chlorine or available chlorine becomes proportional to the added chlorine is called the "breakpoint" in the chlorine demand curve. The introduction of breakpoint chlorination usually results in material improvement in the sanitary quality of a water. When liquid chlorine is added to ordinary surface water, clear and not highly contaminated, in the proportion of about 0.5 to 1 part of "available chlorine" per million gallons, the ordinary intestinal bacteria are destroyed, including such pathogenic forms as the typhoid bacillus. Certain of the enteric viruses, such as poliovirus, are more resistant to chlorination than are coliform bacilli, requiring a concentration of more than 0.2 ppm, while a dose as low as 0.1 ppm may be sufficient to destroy the coliforms. The question of the persistence of enteric viruses in treated waters has been pointed up by the occurrence of waterborne epidemics of infectious hepatitis, and has not yet been fully clarified. 14, 16, 18, 27, 32

The tastes and odors in chlorinated waters may be due to an overdose of chlorine caused by inadequate control methods or to the action of chlorine upon compounds present in the water, commonly as industrial wastes. Excess chlorine and tastes caused by chlorination can often be removed by dechlorination with SO₂ or treatment with KMnO₄ or activated carbon. The bactericidal activity of chlorine may be prolonged, particularly in waters containing considerable organic matter, by the simultaneous addition of liquid ammonia with the formation of chloramines.

The introduction of chlorination of municipal water supplies has, in practically every instance, resulted in marked reductions in the incidence of enteric infection, typhoid fever in particular, in this country, but the addition of chlorine or other bactericidal agents is not a cure-all. When a water is sufficiently heavily contaminated, bacteria embedded in particles of organic matter are not killed even in the presence of available chlorine. It is generally agreed that a content of more than 50 coliform bacteria per milliliter indicates pollution too great for successful chlorination.

Chlorine dioxide (ClO₂) also has been applied to the treatment of water. It has the advantages that it destroys algal tastes as well as the chlorophenol taste of certain chlorinated waters and oxidizes organic matter more rapidly than chlorine, thus allowing the maintenance of a chlorine residual in the distribution system. In water solution this substance is decomposed by light to chloric and perchloric acids and

319

oxygen, and is more bactericidal for coliform bacteria than chlorine.

Frequently a combination of filtration and chlorination is desirable, particularly with rapid sand filters. Not only does a preliminary filtration have esthetically desirable features in the cases of turbid waters, but considerably less chlorine is required for treatment than would have been the case had not the greater part of the suspended material been removed.

The chemical treatment of water on a small scale does not always involve expense as a primary consideration, and hence other methods may be used. The treatment of swimming pool water by ultraviolet irradiation adds no tastes or odor to the water and, although considerably more expensive than chlorination, can be used because the scale of operation is small.³¹ Ozone, which is strongly bactericidal, is also relatively expensive and is not commonly used in this country but is used to an appreciable extent in Europe. Chlorination is always available and bromine and iodine have been used also.²⁰

At times the treatment of water becomes an individual matter, as in the case of an army in the field or when a public supply is known to be impure. In the first instance the water may be treated by the addition of hypochlorite in the form of bleaching powder or a solution of sodium hypochlorite or two drops of a 2 per cent tincture of iodine per quart. Hypochlorite tablets and solutions are available for this purpose, and iodine compounds, such as tetraglycine potassium triiodide, have also been made into tablets under trade names such as Globaline, Potable Aqua, and Individual Water Purification Tablets. The last are said to be effective against ameba cycts, cercariae, and certain of the viruses as well as against the common pathogenic enteric bacilli.² In the home, filters, such as the Berkefeld or Chamberland bougies, may be used, but filtration is slow, and care in operation and frequent cleaning are necessary. The simplest and best method of water treatment for the family or individual, however, is simple boiling. Boiling for five minutes is quite sufficient to destroy with certainty the typhoid bacillus and allied forms as well as the cholera vibrio. When waterborne disease is prevalent, or when a water supply is notoriously impure or exposed to chance of infection, boiling is the only wholly safe procedure.

SEWAGE7, 19

Sewage is best regarded as the used water supply of a community and as such is a dilute solution of fecal matter and other wastes. From the hygienic point of view it is an important vehicle in the transmission of enteric infection; hence the manner of its disposal is of considerable significance. The mechanisms of sewage disposal have as their objects: first, the ridding of a community of an ever-present volume of waste and, second, disposal in such a manner that it is not dangerous to other communities.

The complex organic compounds present in sewage undergo the same processes of decomposition that are involved in the breakdown of dead organic matter in nature and are a part of the so-called cycles of elements such as nitrogen, phosphorus, and the like. Any type of sewage treatment, then, is nothing more than a mechanism for bringing about or accelerating these transformations. The organic compounds are first broken down to amino acids, monosaccharides, and the like, which are eventually oxidized completely to carbon dioxide and water in the case of carbon and hydrogen, and to nitrite and nitrate in the case of nitrogen. Bacteria are the active agents in this decomposition and oxidation, the mechanisms of which have been discussed earlier (Chap. Five). Although essentially simple in principle, sewage treatment is in practice a complex problem which cannot be considered at length here.4, 25

In general, however, sewage disposal falls into one of three categories: (1) dilution, (2) partial treatment, and (3) complete treatment. In the first instance the sewage is simply dumped into some body of water where it will not annoy its originators. Here the breakdown and oxidation of the constituents of the sewage occur in nature, and, if sufficient time elapses, no trace remains beyond an increase in nitrate which, in turn, serves as food material for phytoplankton. When this transformation takes place in a flowing stream, the phenomenon is known as the self-purification of streams. The

essential element, however, is not the fact that the water is in movement but that sufficient time elapses for the breakdown and oxidations to proceed to completion. Soil polluted with sewage similarly "purifies itself."

With increasing population densities the disposal of sewage by dilution becomes unsatisfactory because a body of water is not infrequently a water supply to a neighboring community. Some form of treatment, then, becomes obligatory; in other words, the decomposition is made to take place in whole or in part in the various tanks and other devices making up a sewage treatment plant rather than allowing it to occur in natural bodies of water. In practice, treatment takes the form of preparatory processes followed by a period of anaerobic digestion, and then a period of aerobic oxidation. Treatment may be complete even through nitrification, or the partially treated sewage may be disposed of by dilution.

When the disposal of fecal material is an individual or family problem the mechanics involved are somewhat different, but the processes of decomposition and oxidation are essentially the same whether a privy, cesspool, or septic tank is used.³⁵

It will be noted that, although sewage treatment is basically a bacteriological process, the pathogenic bacteria are not involved; their presence is not taken into consideration, nor is there any effort to destroy them except in the rare instances in which the effluent from a complete treatment plant is chlorinated. In one sense, then, sewage treatment is not directed toward the control of waterborne disease. The fact that it is treated, however, is of considerable significance in this connection. When sewage is disposed of by dilution, the typhoid bacillus and related microorganisms, together with enteric viruses, do not multiply; rather, a decline in numbers sets in immediately. and these bacteria do not survive as long in water as in soil, probably not more than a few days or a week and they tend to disappear during sewage treatment, although there is no assurance that pathogens are absent in the effluent from treatment plants.3, 12, 15, 17 Clearly then, fresh pollution is more dangerous than past pollution, and, in a sense, treatment obviates the possibility of such fresh pollution. The economic and esthetic aspects of sewage treatment are, of course, another matter.

Chapter Twelve

THE MICROBIOLOGY OF MILK AND FOOD

Other than the ramifications of a common water supply, the most common vectors of disease of microbial etiology are the wide variety of foods consumed by man. Like

water, these constitute a link between the susceptible individual and the source of infection.

Milk ^{23, 27, 43}

As a vector of infectious disease, milk differs from water in that it is an excellent medium for the growth of many pathogenic bacteria, and from other foods in that it is the only food of animal origin that is consumed in large part in the raw state. Since large quantities of milk are consumed—it is estimated that about 16 per cent of the average dietary in the United States consists of milk and milk products—the importance of this substance in the transmission of disease is evident. The diseases transmitted by milk are: first, diseases of cattle transmissible to man and including bovine tuberculosis, undulant fever, foot-and-mouth disease, and streptococcal infections from infected udders and, second, diseases of man in which the milk serves as the link between man and man, such as typhoid fever, diphtheria, and rarely, certain other diseases such as poliomyelitis.

Sources of bacteria in milk. Unlike water, milk has no native bacterial flora, and it is probable that milk as secreted into the udder of a healthy cow is sterile. The milk in the udder is, however, rarely if ever bacteriologically sterile, for the microorganisms invade the udder via the milk ducts of the teats and the first portion of the milk drawn (foremilk) always contains more bacteria than the last (strippings). There is, further-

more, no bacterial flora that is characteristic of milk; the presence of microorganisms is always a consequence of contamination, and the types of bacteria found are determined by the source of contamination. From this point of view the bacteria of milk fall into two groups: first, those which are present in the tissues of an infected cow and find their way into the udder and, second, those which enter the milk, usually after it is drawn, from sources external to the animal.

Bacteria from infected cattle. Of these microorganisms perhaps the most important is the tubercle bacillus. These bacteria get into the milk directly as a consequence of tuberculosis of the udder, which occurs in 1 to 2 per cent of infected cows, and indirectly by contamination with cow manure when the infectious sputum is swallowed and discharged with the feces. In either case the milk is infective for man, the bovine variety of the tubercle bacillus giving rise, as a rule, to bone and joint rather than pulmonary tuberculosis. Milk may, of course, be infected with human tubercle bacilli from infected persons. A high proportion of the former type of infection occurs when the transmission of this disease is allowed to occur. The disease may be controlled at its source, i.e, by the elimination of infected cattle from dairy herds, a practice which is practically universal in the United States.

A bovine variety of *Brucella melitensis* (the causative agent of undulant fever), *Br. abortus*, infects cattle, producing the disease contagious abortion. This microorganism is excreted in the milk and infects man, producing a mild type of undulant fever. The caprine variety of this bacterium which is present in the milk of infected goats produces a much more severe disease in man. Undulant fever, like tuberculosis, may be controlled by control of the disease in the animal reservoir of infection.

The virus of foot-and-mouth disease, a virus disease of cattle, is excreted in the milk and is thus transmitted to man. The disease in man is mild, however, and not of great public health importance. More important are the streptococcal infections of the udder, designated garget or mastitis. The Hotis test is commonly used for the detection of mastitis; it consists of incubating fresh milk in the presence of 0.025 per cent bromcresol purple for 24 hours at 37° C. A positive reaction, the formation of yellow flakes on the side of the test tube, is dependent upon the presence of the streptococci and of agglutinins in the milk; the growing bacteria are clumped by the antibody and the acid reaction results from the fermentation of lactose. The streptococci of bovine mastitis, Str. agalactiae, are rarely found to be a cause of human disease, but milkborne epidemics of streptococcal infection may be associated with acute udder inflammation in the dairy herd, and the massive and continuous infection occurring in some of the outbreaks of human streptococcal infection indicates that the udders of the cattle were infected. It has been suggested that Str. pyogenes may proliferate, with or without symptoms, in the udder, and epidemics of human streptococcal infection may occur, though it is probable that in most instances milkborne infection is a consequence of direct human contamination. The udder may be infected occasionally with diphtheria bacilli, which produce small external ulcers, but this is an uncommon occurrence.

Bacteria from external sources. When milk is collected under ordinary conditions, the udder bacteria form but an insignificant fraction of the total number of microorgan-

isms in the milk. The skin of the cow, the hands of the milker, the vessels used for collection, and the dust of the cow barn all contribute their quota to the number of bacteria found immediately after milking. If milk is obtained with aseptic precautions, it contains only a few hundred (200 to 400) bacteria per milliliter; collected with somewhat less care, it may contain a few thousand (2000 to 6000); with careless manipulation, even freshly drawn milk may be highly contaminated (30,000 to 100,000 per milliliter). If milk is kept at 0° C. (32° F.), it shows a decrease in the bacterial content during the first few hours, but at higher temperatures the rate of multiplication is high and, when richly seeded at the outset, enormous numbers of bacteria result.

The nonpathogenic bacteria that are present in milk are often differentiated on a physiological basis into the following groups:

- (1) The acid-forming bacteria
- (2) The alkali-forming bacteria
- (3) The proteolytic bacteria
- (4) The inert bacteria

The first group includes the fermentative bacteria, and the most common type of fermentation is the lactic acid fermentation, the process by which milk usually sours under natural conditions. A variety of bacteria may be responsible, among them Staphylococcus aureus, Str. pyogenes, and Escherichia coli. A few species, however, are commonly active in the natural souring of milk, and these may be divided into two groups. One of these is comprised of the capsulated gas-forming bacilli of the Bacterium (lactis) aerogenes type, which are closely related to E. coli, differing principally in their possession of capsules, lack of motility, and ability to produce gas from potato starch. The second type, a streptococcus, Streptococcus lacticus (or lactis), is abundant in naturally soured milk, particularly when the acidity is high.

Lactic acid milks, regarded by some as having therapeutic value in the treatment of certain intestinal disorders, have been prepared by the inoculation of Lactobacillus species such as *L. acidophilus* and *L. bulgaricus*. The lactobacilli are commonly found in the fermentation of ensilage and are present in small numbers in the human mouth and intestinal tract and are not ordi-

narily responsible for the natural souring of milk.

Although lactic acid is commonly the predominating acid in the fermentation of milk, the formation of butyric acid is observed occasionally. This is generally a consequence of the presence of the anaerobic butyric acid bacteria but may be brought about by *Bacillus subtilis* and related sporeforming aerobic bacilli.

The spontaneous alcoholic fermentation of milk is less usual under natural conditions than either the lactic or the butyric, and the preparation of certain alcoholic beverages is dependent upon the artificial production of this form of milk fermentation. Koumiss, a drink prepared by Tartars by the alcoholic fermentation of mare's milk, and kefir, an effervescent sour milk prepared by inhabitants of the Caucasus from the milk of cows, goats, and sheep, are prepared by the inoculation of fresh milk with old koumiss in the first instance and with "kefir granules" in the second. The bacteriology of the koumiss fermentation is not well known, but in the case of kefir both a bacterium and a yeast appear to be involved. Some species of yeast are able to effect the alcoholic fermentation of milk in pure culture.

The alkali-forming bacteria are those organisms which do not ferment lactose but, presumably, act upon the nitrogenous substances present with the liberation of ammonia. When typhoid and paratyphoid bacilli, for example, are cultivated in litmus milk no effect is apparent beyond a slowly increasing alkalinity. Certain other bacteria, such as some of the aerobic spore-forming types, also produce lipase and decompose the fats present, converting the milk to a yellow transparent fluid.

The proteolytic bacteria also produce an alkaline reaction and, in addition, hydrolysis of the milk protein. Two enzymes or groups of enzymes, are responsible; one, a rennin-like enzyme, precipitates the protein with the formation of a soft curd, and a second, casease, brings about hydrolysis of the protein which, when complete, results in the conversion of the milk to a clear fluid, a process sometimes termed peptonization. Peptonization, however, does not follow precipitation when the microorganism does not possess casease. The bacteria producing these changes include spore-

forming aerobes such as *B. subtilis*, certain strains of staphylococci, *Proteus vulgaris*, and others. Proteolysis may occur in heated milk in which the nonspore-forming lactic fermenters have been destroyed, leaving the more resistant spore-forming proteolytic forms.

The "diseases" of milk. A series of unusual or abnormal changes, called "diseases" of milk, sometimes occur. "Blue milk," "red milk," and "yellow milk" are caused by the presence of various chromogenic bacteria. "Bitter milk," characterized by a bitterness that sometimes develops after a short interval, is likewise due to the products of certain microorganisms. Milk sometimes suffers from a ropy or slimy fermentation which, under most circumstances, is regarded as undesirable, although such a fermentation is intentionally produced in the manufacture of Edam cheese in Holland through the action of a particular species of streptococcus.

The inert bacteria are those which produce no visible change in milk. These include certain nonpigment-forming bacteria from water and other sources, and, in addition, most of the pathogenic bacteria found in milk. Such dangerous contamination, then, is inapparent without bacteriological examination.

The pathogenic bacteria from external sources.40 The multiplicity of sources of contamination results in the heterogeneous bacterial flora that may be found in milk. It is important from the hygienic view that, in addition to microorganisms of soil and water, the bacteria carried by man have relatively ready access to milk. The contamination with the bacteria of human disease is a constant possibility, not only when the milk is drawn but throughout its handling until it reaches the ultimate consumer. Contamination may be direct, as in the case of streptococci or diphtheria bacilli from the throat and typhoid bacilli from the hands of infected individuals, or it may be indirect, as when the water used to wash the milk cans is contaminated with typhoid bacilli. In any case, the microorganisms do not simply survive, as in water, but actively multiply and may be present in huge numbers in pooled milk of which but a single part was originally con-

Clearly, then, the most important factors

governing the number of bacteria which may be present in milk are, first, the kind and degree of initial contamination and, second, the temperature at which the milk is kept. The production of hygienically satisfactory milk, therefore, involves cleanliness in the first instance, and immediate cooling and storage at a low temperature in the second.

The bactericidal property of fresh milk. As indicated above, the number of bacteria present in freshly drawn milk frequently shows an initial decrease. Its extent may be exaggerated by plate counts; the various antibodies are present in the milk, not only the bactericidal substances but the agglutinins as well, which, by clumping the bacteria, may bring about decreased plate counts. That freshly drawn milk is both bactericidal and bacteriostatic, although to a mild degree, is, however, definitely established. This activity is thermolabile. being destroyed in 15 minutes at 75° C. and in two minutes at 80° to 90° C., and disappears a few hours after the milk has been drawn.

The determination of the quality of milk. By far the best index of the quality of milk is the number of bacteria it contains. The bacteria present are, in all cases, a result of contamination, and hence these microorganisms are reliable indicators of cleanliness and care and are generally used for this purpose.

Plate counts. The total bacterial count of a milk is a reflection of its hygienic quality, and the plate count has been, and still is, widely used in the bacteriological grading of milk. Standardization of the mediums and of the technique is necessary for com-

parable results. A standard procedure has been developed under the auspices of the American Public Health Association.²

Standards of milk quality in terms of plate counts are in general use but vary from one locality to another. In some instances more than one grade of milk is allowable; for example, a "Grade A" milk may contain not more than 30,000 bacteria per milliliter as delivered, and a "Grade B" milk not more than 100,000. There is a steady movement toward more strict reguirements, and the maximum number of bacteria allowed is continually reduced. More than one grade of milk is undesirable in that the distribution of inferior milk is allowed, and, when possible, a single standard is preferable. In Chicago, for instance, there is but one grade of milk, and it must not contain more than 10,000 bacteria per milliliter as delivered to the consumer.

The membrane filter technique used for the bacteriological examination of water (Chap. Eleven) is not useful for the routine examination of milk. It is not possible to pass significant quantities of milk through the filter disc without clogging, and if this method is applied the bacteria must first be removed by centrifugation and filtered after resuspension in buffer or saline. It may be applied to equipment rinse solutions, etc.

Microscopic counts. Besides the ordinary macroscopic colony count obtained by plating, a microscopic method devised by Breed is of value for many purposes. In the Breed method milk is taken in a capillary pipette discharging 0.01 ml. and is dried over an area of 1 sq. cm. on a glass slide. After washing out the fat with xylol and fixing with alcohol, the film is stained with

Milkborne Epidemics of Disease*

^{*}In New York State exclusive of New York City as reported by Dublin, Rogers, Perkins, and Graves. 16

methylene blue. The number of bacteria per square centimeter is estimated by counting a measured area. The ratio used in comparing the microscopic count with the standard plate count is 4:1, although it is recognized as inaccurate and variable. This direct microscopic count does not involve incubation and has proved of special value in judging the quality of fresh milk as delivered to milk-receiving stations.

Methylene blue reduction.34 If a small amount of methylene blue is added to milk and the mixture incubated, the dye will, in time, be reduced to the colorless leuco base. Although freshly drawn milk has some small power to reduce this and other dves. the reduction is, for all practical purposes, a consequence of the metabolic activities of contained bacteria. There is, then, a direct relation between the time required for reduction and the number of bacteria present, and the measurement of this reduction time provides a useful approximation of the quality of a milk. The method is best adapted to raw milk and has the great advantage that no special apparatus or training of the operator is required. Although milk cannot be graded with any degree of precision in this way, it is generally agreed that a milk decolorizing in less than two hours is poor in quality, while that which does not decolorize in eight hours is excellent. Resazurin has been used to some extent in the place of methylene blue.

Coliform count. The coliform index of water pollution is not generally applicable to milk. Water contamination of sanitary significance is fecal, but this is not the case with milk; coliform bacilli, for example, would not be associated with the presence of the diphtheria bacillus in milk. Further, since the great majority of market milks contain cow feces, the estimates varying from 60 to 100 per cent, coliform bacilli in milk are probably most often of bovine origin. Although the coli count has been used widely in the past, it is not worth while except under special circumstances.

The isolation of pathogenic bacteria. In contrast to water, the isolation of pathogenic bacteria from milk is not only a practical but often a desirable procedure. The presence of tubercle bacilli, for example, can be conclusively shown only through their isolation, in this instance usually by guinea pig inoculation. Other pathogens,

such as hemolytic streptococci and Brucella, may be isolated by culture. The isolation of these bacteria is not a routine procedure but may be carried out when an outbreak of disease is suspected of being milkborne.

Cell count and sediment test. The number of leucocytes present in a sample of milk and the amount of contained dirt that can be strained out through a standard cotton disc are frequently of value in the assay of milk quality. Excessive numbers of leucocytes are present in the milk from infected udders, and when their presence is noted in Breed smears, mastitis is suggested. The amount of sediment that a sample of milk contains is an index of the extent to which it has been contaminated and is often, though not necessarily always, correlated with the bacterial count.

The hygienic control of milk.⁴⁶ The sanitary quality of milk may be controlled in one or both of two ways: in the first instance, by preventing to a considerable degree the contamination of milk and the multiplication of contained bacteria and, in the second, by destruction of bacteria, the pathogenic forms in particular, already present in the milk.

Inspection. The periodic inspection of dairy farms is carried out by the local board of health in many places and, although it does not insure the absence of pathogenic bacteria from milk, it is effective in increasing cleanliness and reducing the numbers of bacteria. A score card is frequently used, and a given dairy farm is rated according to a system of points.

Certified milk. One of the earliest attempts to avoid the dangers of milkborne infection was the elaboration of methods designed to safeguard milk at every step in its production, collection, and distribution. To this end "Medical Milk Commissions" were established in a number of localities in the United States, usually under the auspices of the local medical society. Milk conforming to certain standards is certified by such a commission to be of high quality. The regulations, which are generally excellent, deal with such matters as the cleanliness of barnyard and dairy, the purity of the farm water supply, the proper sterilization of utensils, and the health of the cows and of the milkers. The bacterial content is limited to 10,000 per milliliter, and the milk must be delivered within 36 hours.

Certified milk is undoubtedly safer to use than milk collected and transported without suitable supervision, and the work of the milk commissions did much to improve dairy conditions in many parts of the country. At the same time, raw milk, certified or not, can never be regarded as protected against all chances of contamination; the difficulty-not to say impossibility-of making sure that no typhoid carriers and no persons suffering from a mild case of diphtheria or scarlet fever are ever employed in a dairy is self-evident. Outbreaks of diphtheria, paratyphoid fever, and other diseases have, in fact, been traced to certified milk. For this reason, as well as because of the relatively high cost of production, the use of certified milk remains limited.

Pasteurization. The process of destroying pathogenic bacteria in milk is by far the most satisfactory method of controlling milkborne infection. The use of a temperature high enough to kill most microorganisms but not so high as to produce radical alterations in the substance heated was first applied by Pasteur to preserving wines without destroying their original flavor or bouquet. Although still widely used in connection with bottled beer and wines, the process of pasteurization is now used chiefly for the treatment of milk.

The temperature to which milk is raised and the time for which it is held there are dictated by the heat resistance of the bacterium to be killed. From the beginning attention has been directed primarily toward the tubercle bacillus, and it has been found that this bacterium is killed by exposure to a temperature of 140° F. for 20 minutes. In practice, then, a temperature of 142° to 145° F. for a period of 30 minutes provides an adequate margin of safety, and these are the requirements that are usually specified. The technical aspects of such treatment of milk on a large scale are of prime importance, taking the form of prevention of foaming, proper design of valves to prevent "cool pockets" and dead ends, and the like. It might be supposed that a higher temperature or longer holding time resulting in a greater margin of safety would be desirable; this is not the case, for if either the time or the temperature is increased alterations take place in the physical state of the milk in which the fat is dispersed into smaller globules and will not rise to the top on standing.

Pasteurization may also be accomplished by the application of higher temperatures for shorter times, 160° to 161° F. for 15 seconds, in the so-called flash or HTST (high temperature short time) process. Unless the milk is preheated and the process precisely controlled, it may not be quite as effective as the holding process, and it has been reported that Brucella will survive HTST without preheating. There is also some tendency for the process to affect the physical qualities of the milk.

The plate count of milk is tremendously reduced by pasteurization, for not only are the pathogenic bacteria, such as the tubercle bacillus, *Br. abortus*, streptococci, and the like, destroyed, but the majority of other bacteria present as vegetative cells are killed also. There appears to be some question of the efficacy of pasteurization, particularly the HTST process, in the destruction of Q fever rickettsiae for, while this disease does not seem to be milkborne, rickettsiae introduced experimentally are not invariably destroyed by either pasteurization process.

The phosphatase test is based upon the presence of the heat-sensitive enzyme phosphatase in milk. Since 96 per cent of the enzyme is destroyed by heating to 143° F. for 30 minutes, the amount remaining in a pasteurized milk may be used as an indicator of the pasteurization as carried out. The enzyme liberates phenol from phosphoric-phenyl esters, and, as originally proposed, the test consisted of the addition of disodium phenol phosphate and Folin's reagent, incubating 18 to 24 hours, and reading the blue color developed.

Not all bacteria are killed by pasteurization. Besides the resistant spore-formers. aerobic and anaerobic, certain streptococci are able to survive the pasteurizing temperature. These are the lactic acid-formers rather than the pathogenic forms, and pasteurized milk sours in the ordinary way on standing, though a longer period is required i.e., its keeping qualities are improved. If higher temperatures are used (180° F.), the lactic acid bacteria are killed and proteolysis occurs as the milk spoils. Thermophilic bacteria are frequently present in pasteurized milk in great numbers, for the temperature of pasteurization is an incubation temperature for these microorganisms. The slight acid metallic taste occasionally noticeable in pasteurized milk is often attributable to their activity.

The presence of thermophilic and other thermoduric microorganisms in milk is taken as indicative of faulty farm sanitation, provided that the equipment of the processing plant is not contaminated with these forms as is sometimes the case. On the other hand, the presence of psychrophilic bacteria in pasteurized milk, such as Pseudomonas, Alcaligenes, and Achromobacter, not only detracts somewhat from the keeping qualities of the milk, but is almost always an indication of poor plant sanitation practices, i.e., represents post-pasteurization contamination.

The process of pasteurization, while effective in destroying pathogenic bacteria present in milk and, incidentally, increasing its keeping qualities, is not to be regarded as an excuse for the marketing of dirty and highly contaminated milk. There is some evidence, for example, that the growth of enormous numbers of bacteria, even though nonpathogens in the usual sense, is associated with summer diarrhea of infants. In most cases, therefore, sanitary regulations specify not only the allowable number of bacteria in pasteurized milk as delivered but also an upper limit for raw milk which is to be pasteurized.

The regulation of milk quality. The application of appropriate methods of rendering and keeping milk satisfactory from the hygienic point of view is, essentially, a social and legal problem rather than a scientific one. To this end appropriate ordinances are more and more generally incorporated into the legal structure of the community, and these, when adequately enforced, produce a marked reduction in milkborne disease. About half the cities of over 1000 population grade milk and permit the sale of one grade of raw milk and one grade of

pasteurized milk; of the total volume of market milk about 74 per cent is pasteurized, 99.4 per cent is from tuberculin-tested herds, and 35 per cent from abortion-tested herds. In general, sanitary regulations are somewhat more strict and more rigorously enforced in the large cities. In Chicago, for example, all milk is pasteurized, including certified milk, and this regulation is rigidly enforced.

Such practice has resulted in marked reductions in the number of bacteria in market milk. In 1901 the bacterial content of market milk in New York City varied from 300,000 in the coldest weather to 5,000,000 during the summer months; in Chicago (1904) the counts ranged from 10,000 to 74,000,000, and in Boston (1892) averaged 4,500,000. The incidence of milkborne disease has correspondingly decreased; for example, in 1907–1915 there were in Massachusetts 2215 cases of typhoid fever which were traced to milk, but in 1919–1923 only 297.

Milk products. Various foods made from milk, such as ice cream, butter, cheese, and the like, are potential vectors of disease when made from milk contaminated with pathogenic bacteria. The bacteria tend to die out upon storage, although it has been found that the typhoid bacillus will survive for three months or more in butter, and tubercle bacilli have been found in butter and certain quick-ripening varieties of cheese. Ice cream may serve as a vector for typhoid fever, streptococcal infection, etc. Pasteurization of the mix is customary and generally at higher temperatures than those used for milk. Human infections with foot-and-mouth disease have been traced to contaminated butter and cheese, but the public health significance of these findings is problematical.

Food Poisoning and Foodborne Infection 12, 13, 17, 42

The diseases transmitted by milk and milk products may be disseminated by a variety of other foods; in addition to these, however, other types of illness may result from the ingestion of contaminated foods which make up that group of affections designated as food poisoning. The kinds of

illness that may result from the ingestion of food may be summarized briefly:

- (1) Individual idiosyncrasies
- (2) Toxemia from foods, such as
 - (a) Foods naturally poisonous
 - (b) Foods into which poisons have been accidentally introduced

- (c) Foods containing poisons of bacterial origin formed by
 - 1. Clostridium botulinum
 - 2. Staphylococci
- (3) Foodborne infection, including both
 - (a) Bacterial infections, such as
 - 1. Typhoid fever, dysentery, and cholera
 - Salmonella infection
 - (b) Parasitic infections

In some instances food serves simply as a vector in the transmission of diseases such as the parasitic infections and the enteric diseases. In the remainder, however, the clinical manifestations are those associated with food poisoning proper vomiting, diarrhea, enteritis, and a greater or lesser degree of prostration. Although a number of types of food poisoning given above are not bacterial in origin, their clinical character may simulate bacterial food poisoning, and these must be considered in any attempt to ascertain the etiology of a given outbreak. Hypersensitivity to a given food substance, for example, is frequently manifested as vomiting, and an outbreak confined to a family may be the result of familial tendency; similarly, the gastrointestinal disturbances following the ingestion of naturally poisonous foods such as toadstools, or foods contaminated with poisons such as arsenic or cyanide, are often indistinquishable from those induced by some poisons of bacterial origin.

FOOD POISONS OF BACTERIAL ORIGIN

Poisoning with food containing toxic substances of bacterial origin is very common, probably more so than is generally recognized. The term "ptomaine poisoning" is a misnomer that is both misleading and inaccurate. The organic bases such as putrescine, cadaverine, methylamine, and the like, called ptomaines, which result from the bacterial decomposition of protein, are not toxic when given by mouth. Neither are other decomposition products toxic per os. While a partially decomposed food may be esthetically unattractive, the innocuous nature of the products of decomposition is obvious when one considers the advanced state of decomposition reached by some cheeses. Toxicity is, on the contrary, attributable to the presence of substances synthesized by the bacteria whose presence may or may not be associated with obvious evidence of decomposition of the food substance.

Botulism. Botulism is a highly fatal form of food poisoning resulting from the ingestion of preformed toxin of one or another of the types of Clostridium botulinum (Chap. Twenty-nine). These toxins are neurotoxins and among the most potent poisons known (Chap. Nine). The separation of these microorganisms into types, designated by capital letters, is made on the basis of the immunological specificity of their toxins; i.e., there is no cross-neutralization by antitoxin with the exception of the subtypes of type C. Botulism in this country is usually due to type A or type B; more recently type E, prevalent in Japan and also found in the Scandinavian countries, has been responsible for botulism in this country and Canada.

Cl. botulinum is commonly present in soil, existing as a saprophyte, for infections are extremely rare. Soil, then, represents the source of infection of food in the case of types A and B. Type E botulism has been associated with the consumption of fish products, and the microorganism has been isolated from the intestinal contents of fish from the Great Lakes, with an incidence as high as 9 per cent in Lake Michigan, and 57 per cent in Green Bay.⁴ A sixth type, type F, described in 1960 and associated with human botulism from liver paste in Denmark, has also been isolated from salmon from the Columbia River.¹¹

Given contamination of foods with Cl. botulinum, there are two prerequisites for the formation of toxin. First, since the microorganisms are obligate anaerobes, anaerobic conditions are required for growth, and these are provided in foods which are canned or sealed as in sausage casings, plastic wraps, etc. Second, a period of incubation is required, and this offers no difficulty for such processed foods are considered to be preserved and are stored, often for considerable periods of time, without refrigeration. Under such circumstances, the bacilli grow and form toxin, with perhaps only slight if any overt evidence of spoilage. As described elsewhere (Chap. Nine), the botulinum toxins are relatively resistant to enzymatic digestion, and in fact those of types A, B, and E may be split to lowermolecular-weight active fragments by proteolytic digestion and are, therefore, effective by the oral route.

Outbreaks of botulism occur as groups of small numbers of cases, the individuals who have consumed the toxic food. Botulism of types A and B in this country most often involves home canned foods, particularly neutral foods such as green beans which are difficult to sterilize and may have been put up by a cold pack method. Such outbreaks tend to occur in rural areas.

A typical history may include the serving of the food at fault, some agreement that it tasted a little abnormal, and discarding of the remainder, for example, by feeding it to chickens. Chickens are susceptible to botulism, a characteristic sign being paralysis of the neck muscles to produce "limberneck." Symptoms of human botulism follow within a day or two. Antitoxin is effective but only prophylactically, since symptoms are the result of nerve damage, which antitoxin cannot repair. If some of the food is available it may be injected into experimental animals, some of which are passively protected with antitoxin. Or the microorganism may be isolated and identified on the basis of its toxigenicity.

Until the appearance of type E botulism, commercially canned food had not been a cause of botulism for many years; regulations for commercial processing are laid down by the Food and Drug Administration and are highly effective. A total of 1561 cases of human botulism have been reported as occurring in this country between 1899 and 1963,35 including those due to type E since 1932. In Europe botulism has been more often due to sausage (hence the name) of one kind or another than to canned vegetables.

Type E botulism has involved fish and fish products for the most part, as indicated above. A raw fish preparation, izushi, has been the most common vehicle in Japan.⁴⁴ Uncooked fish has been involved in this country also, notably smoked whitefish (chub) from the Great Lakes, which had been packed in plastic bags and distributed through a supermarket chain.45 An outbreak due to canned tuna fish28 was the first instance of botulism from a commercially canned food in this country for 40 years. The spores of Cl. botulinum type E are less resistant to heat than those of the other types, and the bacilli grow in small pieces of muscle tissue at unusually low temperatures. 15

Staphylococcal food poisoning. Like botulism, staphylococcal food poisoning is a consequence of the ingestion of preformed toxin. The enterotoxin is usually produced by strains of staphylococci which are virulent by the usual criteria, i.e., golden-pigmented Staphylococcus aureus, strongly hemolytic on blood agar and coagulasepositive (Chap. Sixteen). In one series of such strains of hospital origin about 10 per cent were found to be enterotoxigenic.22 There seem to be no distinguishing morphological or physiological characteristics associated with enterotoxin-producing strains.

Production of enterotoxin is maximal on semisolid brain heart infusion agar⁵ and diffuses into the surrounding medium. Its action is central rather than local, and it produces vomiting and diarrhea in man after an incubation period of two to six hours, with recovery in 24 to 48 hours. The monkey is the only susceptible experimental animal. The enterotoxin is effective by the oral route in a dose perhaps ten-fold that required to elicit a response in man. A gastroenteritis is produced30 and the outward symptoms are much less marked than in man, usually consisting of vomiting a few times within a period of about five hours. It is also effective intravenously in the monkey. A kitten test has been described repeatedly, but it appears to be relatively nonspecific.

Enterotoxin has been prepared in a highly purified form and has been found to be a protein having a molecular weight of 35,000 to 40,000. It precipitates with specific antiserum⁶ in the gel diffusion test developed by Surgalla and his associates, and has been found to occur as two immunological types, designated enterotoxin A and enterotoxin B. More recently a third immunological type, enterotoxin C, has been described.³ The enterotoxins so differentiated do not appear to differ in their activity.

The foods involved in staphylococcal food poisoning are most often starch-containing materials such as custards used in cakes and eclairs, gravies, dressings, salads, etc., but enterotoxin is produced in meat also. The source of infection may be a product such as bulk eggs, but probably more often is an infected person, such as a nasal carrier or one having an open abscess, who prepares the food in question. Contamination may persist in inadequately

washed implements such as pastry-tubes. Custard fillings, salads, etc. are not cooked after preparation, and the penetration of heat into foods which are subsequently cooked is often insufficient to kill the relatively resistant staphylococci. Before it is consumed, the food may remain for some hours at room temperature, as on a shelf or in a showcase or en route to a picnic, to provide the incubation period necessary for growth and enterotoxin production by the staphylococci.

The identification of an outbreak of food poisoning as staphylococcal in etiology has usually been inferential: i.e., the vehicle is defined on epidemiological grounds and is found on culture to contain enormous numbers of staphylococci. Ordinarily, human volunteers or monkeys are not available to test the toxicity of the food or the enterotoxigenicity of the isolate. With refinement of the gel precipitation reaction as a slide double diffusion test, as little as 1 µg. per milliliter of enterotoxin may be detected and applied to appropriate concentrated extracts of the food in question.7 Under laboratory conditions, and using deliberately contaminated foods, enterotoxins A and B could be identified serologically in 40 to 70 per cent of cases. This kind of test has been described²¹ as more or less routinely applicable, but as yet has not been generally used.

This kind of food poisoning is very common, much more so in this country.²⁶ than in Europe, where foodborne Salmonella infections (see below) account for the great majority of food poisoning outbreaks.^{36, 38}

FOODBORNE BACTERIAL INFECTIONS

Whether other kinds of bacteria thought to be associated with food poisoning—because of their presence in very large numbers in foods incriminated on epidemiological grounds—produce enterotoxins is questionable. For the present such association, if it is truly etiological, may be considered to be foodborne infection

The foodborne infections are of two general kinds. On the one hand, a number of diseases, largely enteric diseases in which the oral route represents the usual

portal of entry, may be transmitted by food, but with the production of symptoms characteristic of those diseases. On the other, foodborne infection with some kinds of bacteria results in disease characterized by sudden onset, vomiting and diarrhea, and remission of symptoms within a relatively limited time—in short, a food poisoning syndrome.

The first kind of foodborne infection includes diseases such as bacillary and amebic dysentery, typhoid and paratyphoid infections, and cholera, in all of which the symptoms and course of the disease are characteristic of those produced by the microorganism and do not resemble those of food poisoning.

Foodborne typhoid, dysentery, and other diseases of the first group ordinarily occur on a small scale; the great epidemics are waterborne and, to a lesser extent, milkborne. Although limited in scope, foodborne infection plays an important part in maintaining some of these diseases in endemic form. The so-called residual typhoid, for example, which remains in spite of hygienic control of water and milk supplies is, in large part, foodborne. The employment of cooks and other food handlers who are typhoid carriers provides the opportunity for food infection and consequent transmission of the disease.

In contrast, a number of kinds of bacteria producing a foodborne infection with symptoms characteristic of food poisoning have been described, including streptococci and coliforms. Among such bacteria, an etiological relationship has been firmly established only in the case of Salmonella and Clostridium welchii.

Salmonella food poisoning. Of the Salmonella infections, one of three species is generally involved: Sal. typhimurium (Sal. aertrycke) and its varieties (newport, stanley, etc.), Sal. enteritidis, and Sal. choleraesuis (including Voldagsen and paratyphi C). Sal. typhimurium is the most frequently observed, while Sal. cholerae-suis is only rarely present. The ingestion of food containing large numbers of these organisms frequently results in the typical symptoms of food poisoning. No enterotoxic substance has been shown to be formed by these bacteria, and it is probable that actual infection takes place as indicated by the somewhat longer incubation period and the finding of the bacteria in the feces. The case fatality is variable, ranging from zero to 10 per cent. Almost any kind of food may serve to carry these microorganisms, although meats and other protein foods predominate.

Both Sal. typhimurium and Sal. enteritidis are commonly carried by rats and mice, and it is probable that in many cases these rodents are responsible for the infection of food. In others the source of infection may be a human carrier, and in many cases of meat poisoning it has been found that the meat was from a diseased animal.

As in the case of staphylococcal food poisoning, there is usually a history which includes a possible, or probable, source of contamination and storage of the contaminated food under circumstances allowing bacterial growth. The identification of the etiologic agent found in the food is a routine laboratory procedure, involving isolation and identification by the conventional cultural and serological methods (Chap. Twentyone).

Clostridium welchii food poisoning.25 The association of the sporulating obligate anaerobe Clostridium welchii, a causative agent of gaseous gangrene (Chap. Twentynine), was found by McClung³¹ in 1945 to produce food poisoning in man. The etiology of this kind of food poisoning is now well established, and outbreaks are reported with increasing frequency,37 probably a consequence of more careful search for this microorganism. In California the number of outbreaks of food poisoning attributable to Cl. welchii increased four-fold between 1960 and 1961, and in the latter year accounted for 17.5 per cent of all persons affected by food poisoning.29 Similar increases have been observed in England, with perhaps one-quarter of all cases of food poisoning being attributable to Cl. welchii.

Not all strains are active, and there seem to be no differential characteristics of food poisoning strains.²⁰ This kind of food poisoning has been produced experimentally in human volunteers, and it was found that cell-free culture filtrates or boiled cultures were not effective, indicating that this kind of food poisoning is a mild infection.¹⁴ Meat, particularly poultry, is most commonly the vehicle of infection. The food involved in

the first reported outbreak was chicken salad. Consistent with this, it has been found^{32, 41} that contamination with *Cl.* welchii is not uncommon in poultry.

Shellfish and disease. Shellfish, including ovsters, clams, and mussels, have been responsible for the transmission of enteric disease, especially typhoid fever and more recently infectious hepatitis, through pollution of areas in which they are grown or stored. They are commonly eaten in an uncooked or partially cooked condition which facilitates transmission of disease; it has been found that, while scalloped ovsters, fried clams, and clams in chowder are practically sterilized, steamed clams, fried ovsters, ovsters in stew, and mussels cooked in the usual ways are not freed from coliform bacteria. The shellfish, in the course of breathing and feeding, filter large quantities of water and readily take up enteric pathogens from polluted beds or when placed in brackish waters near sewage outfalls to "fatten," in effect concentrating the pathogen. They are similarly contaminated with viruses, as indicated epidemiologically by the occurrence of foodborne epidemics of infectious hepatitis.9 Various enteroviruses, including ECHO and Coxsackie viruses, have been isolated from ovsters taken from contaminated waters33 and. under experimental conditions, have been found²⁴ to take up poliovirus and Coxsackie virus, with persistence of the virus for as long as 28 days.

Imbibed bacteria, however, if not ejected very soon, are passed through the gastrointestinal tract and discharged in about five hours. The rapidity with which bacteria are passed through shellfish suggests the possibility that they may be cleansed of infection by storage in clean or even chlorinated water. The possibility is not only feasible but practiced, four days sufficing to eliminate practically all coliform bacteria. Essentially the same methods used for the bacteriological examination of water are applied to shellfish. The United States Public Health Service has suggested that not more than 50 per cent of the 1 ml. samples of pooled shell liquor and finely chopped tissue of 10 or more oysters, clams, or mussels should show coliform bacteria in the presumptive test, but the figure is a guide rather than a standard and is flexible.

Light will be to be

FOODBORNE PARASITIC **INFECTIONS**

These include the various flukes, tape worms, echinococcus, and roundworms that infect man. In these diseases the infective stage of the parasite is often present in a food substance as a consequence of its life cycle and the mechanisms involved may be found elsewhere (Chap. Thirty-four).

CONTROL OF FOODBORNE DISEASE

Foods constitute an unusually effective inanimate vehicle of disease, largely because pathogenic bacteria are able to multiply in them to produce toxins and/or give rise to large numbers as an infecting dose. Control of foodborne disease is concerned with the entire sequence of events from the harvesting of the food to its final consumption. In general, it consists of the prevention of contamination, and the destruction of possible contaminants by processing and/or inhibition of their growth in the interval elapsing between such contamination and consumption.

In some instances it is not possible to prevent initial contamination, as by trichina in pork or Cl. botulinum in fish, but for the most part contamination is of human origin. Such sources of contamination are infected persons who handle food. These persons may be casual or chronic carriers or may suffer from transient overt infections. It is possible to control such contamination in part by periodic bacteriological examination and their exclusion from occupations involving food handling. This is a function of health departments, but it cannot be invariably effective. Thus, while many state health departments maintain records of all chronic typhoid carriers and prevent their contact with foods by not allowing them to work in restaurants or other establishments concerned with food preparation, periodic examinations of food handlers may well miss transient infections or carrier states.

Foods may be examined for sanitary quality in terms of the kinds and numbers of microorganisms present. This not only allows an estimate of their quality,39 but also permits inferences as to their history.

It is possible, then, to set up microbiological standards for foods, as is done for water and milk, which may be put upon a legal basis and be enforceable by agencies at one or another level of government, such as the Food and Drug Administration. The introduction of new methods of food processing, as in the case of frozen foods, raises new questions of processing and standards. 18, 19

While the foregoing approaches to the control of the microbiological quality of foods can be applied collectively, essential elements of such control are necessarily individual matters. The exercise of appropriate care in the domestic preparation of food-its storage under refrigeration where indicated, etc. - must be done at the individual and family level.

IMMUNITY

Antigens, Antibodies, and the Antigen-Antibody Reaction^{3, 5, 18, 38, 62}

It has been common knowledge for many years that recovery from certain of the infectious diseases is accompanied by the development of an enhanced resistance, and second attacks of a disease once overcome are not common. This enhanced resistance. or immunity, is specific—i.e., an individual immune to one disease may be no more than ordinarily resistant to others—and is variable from one disease to another, some giving rise to a "solid" immunity of long duration while in others the immunity is imperfect or partial and transient. The specific immune state supplements the complex of factors which make up nonspecific resistance to infection, and even a solid immunity may be broken down by fatigue, malnutrition, and similar factors which are not consistent with a state of physiological well-being.

Specific immunity is a consequence of the reaction of the host to the microorganism and/or its products and provides the basis for prophylaxis of disease or infection. Its development during the course of disease is the primary determining factor in the outcome of the infection.

Historically, immunity, or immunology, was concerned primarily with disease, but it became clear that the basic principles have general biological application that has as vet been limited. Immunological specificity appears to be intimately related to the basis of biological individuality, and makes possible a precise and sensitive characterization of the larger molecular constituents of protoplasm. As such, immunological methods become unique analytical methods applicable to problems such as protein synthesis, blood and other tissue incompatibilities, and phylogenetic relationships, as well as to certain kinds of noninfectious disease or manifestations of disease such as the hypersensitivities.

Here the subject material of immunology will be considered under the general heads of antigens, antibodies, the antigen-antibody reactions, and effective immunity to disease. The differentiation is somewhat artificial and analogous to the separation of virulence and resistance. Antigenicity is demonstrable only by the immune response, and, conversely, antibody is formed in response to the antigenic stimulus.

Antigens 21

An antigen is customarily defined as a substance which, when introduced into the tissues of an animal, provokes an immune response, demonstrable after a latent period by the appearance of antibody in the blood and other body fluids which reacts specifi-

cally with the antigen, by a specific immunity to an infectious disease when the antigen is a pathogenic microorganism and/or its products, or by an increased reactivity, or hypersensitivity, to the antigen.

This definition is that of a so-called com-

336 ANTIGENS

plete antigen which both stimulates antibody production and reacts with the antibody so formed. Other substances have a more limited antigenicity in that, while they react specifically with antibody, they are unable to stimulate antibody formation. These substances are partial antigens or haptenes, and when they are found in microorganisms after destruction or removal of complete antigenic substances, they are called residue antigens.

The partial antigens, or haptenes, are, in turn, subdivided into two groups by some workers. One of these is made up of the haptenes which react with antibody in vitro to give the usual serological reactions (Chap. Fourteen), and the other includes those which react with antibody, but without overt evidence of the reaction, and the antigenantibody reaction is demonstrable only indirectly as an interference or inhibition phenomenon. This last, as will appear, is a consequence of the structure of the haptene and has no relation to its antigenic specificity.

Relative antigenicity. The property of complete antigenicity is variable in that some substances are "good" antigens and give a marked immune response, while others are "poor" antigens and stimulate only a low-grade immune response characterized by, for instance, a relatively ineffective and transient immunity or small amounts of demonstrable antibody, etc. Substances such as ovalbumin, serum globulin, and diphtheria and tetanus toxoids are good antigens, but hemoglobin and nucleoproteins and their constituent histones are poor antigens.

Relative antigenicity must also be evaluated in terms of the animal species in which the immune response is provoked and the way in which the response is assayed; in fact, in some instances it may be difficult to demonstrate antigenicity, or lack of antigenicity, because of variation in the immune response of the test animal. In general, the rabbit and chicken are good producers of precipitating and agglutinating antibodies, but there are differences between the two with respect to the kind of antigen, e.g., the antigenicity of hemoglobin is more readily demonstrable in the chicken than in the rabbit. In contrast, the guinea pig and the rat are not good producers of these antibodies, but the guinea pig is readily sensitized to anaphylactic shock by extremely minute amounts of antigen, and the rat gives a good immune response assayed as protective antibody.

Similarly, certain of the high molecular weight polysaccharides, such as the pneumococcal polysaccharides, are antigenic in man and in the mouse, but not in the guinea pig or rabbit. Relative antigenicity, then, eludes precise definition.

Adjuvants.³² A good immune response requires exposure of the antibody-forming mechanisms to the antigen for an appreciable time, even though the actual synthesis of antibody may be very rapid, and adequate amounts of antigen are required. In the first instance, a single inoculation of an antigen that is rapidly dispersed in the tissues and eliminated elicits only a minimal immune response, and the same amount of antigen is much more effective when given in successive inoculations. In the second, the degree of the immune response is directly related in a limited way to the amount of antigen administered; e.g., the relation between the amount of diphtheria toxoid administered and the antitoxin titer produced is linear over a limited range.

When the antigen is particulate or in a relatively insoluble form it tends to remain in the tissues for longer periods and so provides a more prolonged antigenic stimulus. Killed bacteria are usually good antigens, and living attenuated microorganisms (Chap. Seven) often produce an actual infection in which the amount of antigen is increased over that inoculated and the antigen persists to give a prolonged stimulus. The antigenicity of soluble antigens, or even bacterial vaccines, may be enhanced by the use of adjuvants which precipitate or coprecipitate the antigen in a relatively insoluble form, or otherwise delay its absorption. An antigen depot is established, often at the site of inoculation, from which antigen is slowly dispersed to provide a prolonged antigenic stimulus. A variety of substances have been used as adjuvants, most commonly alum, calcium phosphate, and water-in-oil emulsion containing the antigen. The effectiveness of the last is increased by the inclusion of killed acid-fast bacilli such as tubercle bacilli or related saprophytic forms-the Freund adjuvant. Antigenicity is appreciably, or even markedly, enhanced by such adjuvants. For example, two inoculations of alum-precipitated diphtheria toxoid will give an immune response as good as that produced by three inoculations of the fluid toxoid, and the antigenicity of a poor antigen

may be demonstrable when an adjuvant is used.

While a prolonged antigenic stimulus is undoubtedly a major factor in the effect of adjuvants on antigenicity, other factors are involved also. There is, for instance, reason to believe that the immune response is enhanced by an irritant effect of the antigen or adjuvant to give an inflammatory reaction and accentuation of the response of the antibody-forming mechanisms. This is the rationale behind the so-called nonspecific protein therapy of disease in which substances such as typhoid vaccine are administered. Still other factors are involved also, and the nature of the enhancement of antigenicity by adjuvants is not fully understood.

PROPERTIES OF ANTIGENS

Antigenicity may be further characterized as the kinds of substances that are antigenic, *i.e.*, the properties associated with antigenicity. These are, in general, of three kinds. First, antigens are substances of natural origin that are of relatively large molecular size; second, they are digestible, at least to a certain extent, by enzymes present in the body tissues; and third, they are foreign, or contain structures foreign, to the antibody-producing mechanism of the test animal.

Size and nature. Complete antigens are usually naturally occurring proteins containing a full complement of amino acids, and certain high molecular weight polysaccharides of natural origin may also function as antigens. It is possible that high molecular weight polymers may be antigenic, but with the possible exception of polyvinyl pyrrolidone⁴⁹ none has been found to be antigenic. Large molecular size invariably accompanies the ability to stimulate antibody formation, though all large molecules are not antigenic, and it is probable that molecular weights of 10,000 or greater are essential to antigenicity. There is, in fact, some rough correlation between relative antigenicity and molecular weight in that antigens having molecular weights of less than about 40,000, such as lysozyme, protamines, histones, and insulin, are usually poor antigens. Consistent with this, the antigenicity of a protein disappears rapidly on enzymatic hydrolysis, and proteoses and polypeptides are not antigenic.

A number of derived proteins, notably gelatin, are not antigenic, or only feebly antigenic in conjugated form, even though of high molecular weight. Gelatin is deficient in aromatic amino acids, and it has been supposed that an adequate content of aromatic radicals may be associated with antigenicity, but there is little definitive evidence for this.

Conjugation of an antigenic protein with another substance usually does not impair its antigenicity, and may even enhance it, but often alters its specificity (see below). In fact, many naturally occurring antigens are complexes of protein with other substances, commonly polysaccharides, and good antigens, such as ovalbumin and globulin, often contain carbohydrate as an integral part of the molecule. There are a number of exceptions among naturally occurring complexes; the nucleoproteins are not better antigens than the histone moiety, and a number of glycoproteins are poor antigens.

Degradation. The susceptibility of the antigen molecule to enzymatic degradation in the tissues appears to be a highly significant element of antigenicity. Particulate antigens, such as microorganisms, are phagocytosed and broken down both physically and chemically, and soluble protein antigens are readily metabolized. Not only is it not necessary that the intact antigen molecule persist as such, but there is reason to believe that the immediate antigenic stimulus is, in fact, an active fragment of the antigen which affects directly the antibody-forming mechanism. Such active fragments have not, however, been detected in the products of enzymatic degradation of antigens in vitro. The effect of an antigen depot produced by the inclusion of an adjuvant with the antigen is not one of preventing degradation, but rather of reducing the rate at which degradation occurs to provide a continuing source of antigenic stimulus over a longer time and more efficient utilization of antigen.

The significance of antigen degradation is illustrated in another way in the case of pneumococcal polysaccharide. As indicated above, this substance is antigenic in the mouse, but it is metabolized only very slowly by the tissues and is excreted largely unchanged in the urine. As a consequence, an apparently anomalous situation occurs in which the polysaccharide stimulates antibody formation only when given in minute

338 ANTIGENS

amounts. When larger amounts are administered, the antigen accumulates in the tissues where it is directly demonstrable, blocking the "detoxifying" mechanisms. The animal becomes refractory and will no longer form antibody, a state that has been called "immunological paralysis" by Felton.

Alien nature. The third essential prerequisite of antigenicity is that the antigen be foreign and distinguishable as "not-self" by the antibody-forming mechanism. 12 As pointed out elsewhere (Chap. Nine), the distinction between self and not-self is not made by embryonic or fetal tissue, and the property of making the distinction is usually not fully established until some time post partum, so that the animal immature in this respect is unable to form antibody. This does not invariably hold true, for the fetal tissue of some animal species, notably the fetal lamb, 68 has been found to be fully competent to form antibody. The animal mature in this respect reacts to the foreign nature of the antigenic substance by the formation of antibody except in the extremely rare condition of hypogammaglobulinemia.

The foreign quality of antigens may be of varying degree, ranging from that of antigenic substances of phylogenetic origin widely different from the recipient animal, to isophile antigens or iso-antigens occurring among individuals of the same species and within single individuals. The alien nature of antigens is reflected in the specificity of the antigen-antibody reaction, and widely different antigens appear to be quite unrelated immunologically, closely related antigens show cross-reaction by varying degree with appropriate heterologous antibody and behave as poor antigens when they are closely related to constituent antigens of the recipient animal.

ANTIGENIC SPECIFICITY

In general, antigenic substances from one species of animal stimulate antibody formation in another animal species, and antigens of plant origin are antigenic in animals. The relation between antigen and antibody is highly specific, as indicated above, in that antibody produced in response to the antigenic stimulus reacts specifically with the homologous antigen, and the antigen reacts

specifically with homologous antibody. In a sense the serological methods (Chap. Fourteen) used to demonstrate the antigenantibody reaction are analytical methods, sensitive, roughly quantitative, and highly specific for components of protoplasm which are antigenic.

Species specificity. Serum proteins are among the most commonly used antigens and may be used to illustrate specificity. Serum proteins from the horse, sheep, chicken, man, etc., are antigenic in the rabbit, while rabbit serum protein is not. Similarly, rabbit, horse, etc., serum protein is antigenic in the chicken, and the homologous chicken serum protein is not. Specificity is also expressed in the reaction of antigen with antibody. An antiserum to, for instance, horse serum protein prepared in the rabbit will react in vitro only with homologous horse serum protein antigen and will not react with serum protein from the chicken, man, cattle, etc. This kind of antigenic specificity is commonly referred to as species specificity although it obviously extends beyond the limits of species, through genera, and kingdoms, if plant antigens are considered also.

On the other hand, specificity is less sharp between antigens from closely related sources in that cross-reactions occur; *i.e.*, antiserum to chicken serum protein will also react with pigeon serum protein; antiserum to chicken egg albumin will react with duck egg albumin; antiserum to sheep serum globulin with beef serum globulin, etc.; but the heterologous reaction is weaker than that to the homologous antigen in that it occurs to lower titer than with the homologous antigen. Similar immunological relations occur among plant proteins as, for example, among seed proteins.

Phylogeny. It is a matter of no small interest that the immunological relationships among living organisms parallel their phylogenetic relationships based on a comparative anatomy.³⁴ Among the primates, for example, it was shown by Nuttall at the turn of the century that the Simiidae (gorilla, chimpanzee, orangutan) are very closely related to man in the antigenic specificity of blood proteins; the old world monkeys (Cercopithecidae) are not quite so closely related; the Hapalidae (marmosets) are still more distantly related; and the lemurs, which are Lemuroidae rather

than Anthropoidae, are unrelated to man. Similar relationships occur among other phylogenetic groups, plants as well as animals. It would appear to, and does, follow that antigenic specificity is genetically determined, and this is readily demonstrable within fertility groups; e.g., races of experimental forms such as Drosophila. Paramecium, fowl and other birds may be differentiated on this basis with segregation of antigenic specificities, and the immunological method has become a powerful tool in genetic studies as a measure of individuality. Genetically determined antigenic specificity is of practical significance in man in connection with blood groups and the incompatibilities observed in tissue grafts (see isophile antigens below).

Antigenic specificity has practical application for forensic purposes in the identification of blood protein in blood stains in criminal inquiries and in other areas such as the detection of adulteration of beef with horse meat, etc., and is fully acceptable as legal evidence. For such purposes it is essential that the antiserum used for the identification of unknown antigen be highly specific and without significant cross-reaction. The identity of the antigen may be suggested by relative titers with respect to the homologous antigen, but the specificity of the reaction may be established by absorption of antibody reacting with the heterologous antigen (see below) in some circumstances, or by the choice of animal immunized. For example, it is easy to establish that a blood stain is fowl blood rather than human blood, but the antiserum to human blood will react with the blood of some monkeys as indicated above. Crossreactions do not occur if the antiserum is prepared in the animal whose blood antigens show cross-reaction; thus, while antiserum to sheep serum globulin prepared in the rabbit will react also with beef serum globulin, if the antiserum is prepared in cattle there will be no cross-reaction.

Isophile antigens. Antigenic specificity, then, is at least a part of the basis of biological individuality, and its significance in this respect is underscored by the occurrence of antigenic differences between individuals of the same species alluded to above, the isophile antigens, *i.e.*, those which occur within the species, but not in all individuals of the species. The most important of these are

those characterizing the blood groups and those concerned in the reaction to tissue grafts.

Blood groups. 37, 61, 92, 93 It was found by Landsteiner in 1901 that incompatibilities observed in human blood transfusions have an immunological basis, and that human blood occurs in four immunological groups representing the possible combinations of two erythrocyte antigens. In the international system of nomenclature the antigens are designated A and B, and the combinations A, B, AB, and O, the last lacking both antigens. Antibodies corresponding to these antigens occur in the serum of individuals lacking the homologous antigen; i.e., the antigen and corresponding antibody do not co-exist in the same blood. The serum of the individual having type O blood contains both antibodies, ab; that of the individual having type A erythrocyte antigen, the antibody b; etc. The A antigen is further subdivided into two antigens, A_1 and A_2 ; the type A blood, then, may be A_1A_1 , A_2A_2 , A_1A_2 , A_1O , or A_2O , and so on, in combinations with the B antigens in type AB.

Many additional erythrocyte antigens have been described also. Two designated M and N occur separately and in combination with one another, and with the A and B antigens to give 12 antigenic types of erythrocyte, neglecting the subdivision of A. Another group of erythrocyte antigens, the Rh antigens, so-called because the first of the series was found by Landsteiner and Wiener in the rhesus monkey, also occurs. Antigens of this group are related to erythroblastosis fetalis, a hemolytic disease of newborn infants due to immunization of the mother, who lacks the antigen, by antigen occurring in the erythrocytes of the child by paternal inheritance, and destruction of the infant's red cells by the antibody. The original Rh antigen is designated Rh₀; rh' and rh" are two additional antigens; and Rh₁ and Rh₂ are complexes containing Rh₀ and rh' or rh" respectively. Still additional antigens are associated with this group; viz., hr' is the antigen found in cells lacking the rh' antigen, etc.

Still other blood group antigens have been described to give nine systems including the three noted above, AB, MN, and Rh, and it is probable that still other systems will be defined to include antigens which are not fitted into these groups.

Isophile erythrocyte antigens and the occurrence of blood groups are by no means confined to man and have been described in various lower animals, including rats, cattle, rabbits, and fish.^{77, 81}

There seems to be little doubt that the antigenic specificities of the blood group antigens are genetically determined, probably on a one-to-one relation between gene and antigen, and appear to combine in a simple Mendelian way. So the frequency of blood groups can be regarded as the phenotypic expression of human genotypes and has had valuable application in studies in human genetics. It has been found that there is appreciable segregation of such gene frequencies in subgroups or races of man. For example, 83 per cent of Eskimos have type M antigen in contrast with 57 per cent for Arabs, 28 per cent for English, and 2 per cent for Australian aborigines, and the frequency of type O blood varies from 85 per cent in American Indians, through 47 per cent for English, to 32 per cent for Russians. This subject is treated in detail by Boyd.4,6

Another application of the patterns of inheritance of the human blood group antigens is in forensic medicine in connection with disputed paternity. Comparison of the blood group antigens of mother, child, and possible father can show that a given individual could not have been the father, but cannot establish paternity.

The homograft reaction.^{2, 8, 66, 82, 85} When tissue is transplanted from one part of the body of a mammal to another, providing that it has not been injured in the process, the transplant, or graft, becomes vascularized, grows, and establishes itself permanently. Such a tissue transplant is an autograft; i.e., the donor and recipient are the same individual.

When a similar transplant is made from one individual to another of the same species, the grafted tissue also becomes vascularized, but after a few days or a week the graft tissue is invaded by lymphocytes and plasma cells, the blood vessels become dilated and engorged, the graft begins to be destroyed, and after two or three weeks destruction is complete and the graft is sloughed off. This kind of a graft is a homograft, and its rejection in the kind of reaction just described is the homograft reaction. If a second attempt is made to implant a homograft from the same donor, the reaction is

accelerated, and the graft rejected even more rapidly.

A third kind of tissue graft is the heterograft in which the donor and recipient are of different species. Reaction to the heterograft is even more violent than to the homograft, and the graft is rejected.

The homograft reaction is the consequence of an immunological response to the presence of isophile antigens in the donor tissue, but not present in, and therefore foreign to, the recipient. This effective immune response appears to be largely a hypersensitivity of the delayed type (Chap. Fifteen). Conversely, the graft tissue responds immunologically against the tissues of the recipient, but it is not clear to what extent this affects the rejection.⁷⁶

The isophile antigens concerned are, like the blood group antigens, genetically determined. This was shown in 1927 by the work of Loeb and Wright, who found that homografts between individuals of strains of guinea pigs so highly inbred as to be practically identical genetically took as well, or almost as well, as autografts. When tissue transplants were made between individuals of different inbred strains, they behaved as homografts. Further, the F, generation hybrids of such inbred strains accepted tissue grafts from either parent, but transplants from a hybrid to either parent behaved as homografts, indicating that neither parent contained relevant antigens foreign to the hybrid, but the hybrid offspring contained relevant antigens foreign to each parent which were contributed by the other parent. Human individuals are too heterogeneous genetically to behave in this way, but homografts between identical twins behave as if they were autografts.

The question of tissue incompatibility has been studied at some length in the mouse, and the genetic determinants of the relevant antigenicities are known as histocompatibility genes. A number of these have been described and designated H-1, H-2, etc.; of these H-2 has been the most intensively studied.⁷³

Prior inoculation with a suspension of living tissue homogenate accentuates the homograft reaction just as does previous tissue transplant, but it has been found that prior inoculation with a brei of killed tissue gives a variable, but sometimes enhancing, effect favoring the growth of a tumor homograft and possibly also of normal tissue

homografts. The mechanism of this enhancing effect is obscure. Some workers believe that the killed tissue induces a humoral (circulating antibody) rather than a cellular (Chap. Fifteen) immune response which favors survival of the graft by walling it off, while the living tissue gives a primarily cellular immunity that results in acceleration of destruction of the graft tissue. In this view, the humoral response, if it can be this sharply differentiated, would serve to isolate the graft from the antibody-forming mechanism in the same way that organ-specific and other iso-antigens are isolated.

Iso-antigens. In addition to isophile antigens discontinuously distributed among individuals of the same species, the individual also contains antigenic substances to which he will give an immunological response. These are iso-antigens.

The apparent contradiction is resolved by a more precise definition of the alien nature that is a prerequisite to antigenicity by further specifying, as indicated earlier, that the antigen is foreign to the antibodyproducing mechanism of the animal. Thus substances associated with reticular tissues or highly specialized cells and organs may be effectively isolated from the antibodyforming mechanism and retain sufficient alien nature to function as iso-antigens. There are a number of examples of such iso-antigens. It has long been known, for instance, that thyroglobulin is antigenic within the species, that lactating animals may be able to produce antibody to their own caseins, and that viper serum will protect against the venom of the snake as effectively as the best immune serums. Further, certain organs and tissues contain antigens, which may or may not be organ- or tissuespecific (see below) but which function as iso-antigens.

Auto-immune disease. 41, 47, 80, 84 Under circumstances which are not as yet well understood, an individual may form antibody against his own tissues, resulting in auto-immune disease or collagen disease. The latter term indicates the common involvement of the connective tissue, and disease may take a number of forms, including hemolytic anemia, disseminated lupus erythematosus, idiopathic Addison's disease, Hashimoto's disease (chronic thyroiditis), and possibly also rheumatoid arthritis. The antibodies so produced are demon-

strable in a variety of serological reactions (Chap. Fourteen) such as gel precipitation, complement-fixation, and fluorescent antibody staining. A multiplicity of antibodies is usually found in auto-immune disease, including anticytoplasmic and antinuclear antibodies, and antibodies to leucocytes, red cells, and platelets. Of such antibodies, those to various nuclear components have been of considerable interest, and there is evidence that a delayed hypersensitivity reaction may be involved also.⁶⁵

Heterogenetic antigens. While antigenic substances are, as described above, usually sharply specific for the species or even for the individual, certain antigens occur in different, often widely separated, species, that have the same or closely related specificities. Of these antigens the α-and β-crystalline of the lens protein of the eye, the Forssman antigen, and the organ- or tissue-specific antigens are among the best known.

Forssman antigen. The most extensively studied of the heterogenetic antigens is the common, or closely related, antigenic specificity which is named after its discoverer, Forssman. It is sometimes known as heterophile antigen although it is only one of a group of these substances.

Forssman antigen is present in a variety of phylogenetically unrelated organisms including dogs, cats, sheep, horses, certain fish eggs, turtles, and toads, and certain bacteria including strains of enteric bacilli and pneumococcus, and some varieties of corn (maize). It is not found in rodents except the guinea pig and hamster, nor in rabbits, frogs, hogs, and most primates. When the antigen is present, it is usually found in tissues and organs rather than in the blood, and in the sheep is found in the erythrocyte but not in other cells. Application of the fluorescent antibody technique (Chap. Fourteen) has shown that the antigen occurs in the endothelium and adventitial connective tissues of blood vessels in organs, with some species differences such as its presence in the collecting tubules of the kidney of the guinea pig and chicken, but not in these tissues of the mouse, dog, and cat.87

For a time it was thought that the Forssman antigen was a lipid, since it could be extracted from tissues containing it in ethanol, but it now seems clear that its antigenic specificity is a function of a carbo-

342 ANTIGENS

hydrate group present in the antigen. Its specificity is related to that of the human blood group A substance, and both are related to a fraction of hog gastric mucin, probably through content of similar carbohydrate groups.

The apparently random distribution of Forssman antigenicity is of practical significance in the interpretation of certain immunological reactions. For instance, the hemolytic antibody that lyses the sheep erythrocyte is usually Forssman antibody; in fact, Forssman's original observation was the lysis of sheep red cells by antiserums to guinea pig tissue prepared in the rabbit.

antigens.20 Still Organ-specific antigens whose specificity crosses species lines are those associated with certain organs and tissues. Kidney tissue, for example, contains antigenicity common to this organ from different animal species as well as species-specific antigens. In at least some instances antigenicity is associated with the heavy protein fraction separable from tissue homogenates by high speed centrifugation. They may be in part mitochrondria or, in the case of virus-infected tissues, the viral agent, and from the latter point of view the normal tissue components represent artifacts.26,40

Immunological studies have shown that the heavy proteins from various organs have three kinds of specificity, viz., species specificity, organ specificity related to the same organ in other species, and specificity for the organ of the one species. By the use of labeled antibody as by iodination with I¹³¹ or diazotization with S³⁵-containing compounds, it is possible to show that antibodies to the tissue-specific antigens localize in those tissues, usually in the vascular bed, and tissue-specific lung, liver, and kidney antigens may be demonstrated in this way.⁶⁰

Antibodies to such organ- and tissuespecific antigens may have a cytotoxic effect on the tissue in the intact animal. The kidney has been the most thoroughly studied in this connection, and heterologous nephrotoxic antibody has been found to produce nephritis with gross changes in the kidney, impairment of function as indicated by proteinuria, and histopathology of the glomerular epithelium. Similarly, continued inoculation with vaccines, such as rabies vaccine, containing brain and cord substance may affect the central nervous system by stimulating the formation of antibody which reacts with nerve tissue, and it has been shown that acute disseminated encephalomyelitis may be produced experimentally by the inoculation of homologous brain tissue with adjuvants.⁵⁴

Acquired tolerance. 15, 27, 28, 45, 51, 71 It was pointed out earlier that embryonic tissue does not form antibody, apparently because it is unable to distinguish the foreign nature of an antigenic substance not normally present in that tissue. It is a matter of particular interest that antigenic substances, even though they may be foreign in the sense that they do not occur normally in the individual, may be accepted as self when present in the embryonic tissue even after the capacity to make the distinction between self and not-self is developed. This acceptance, and consequent failure to form antibody to that antigenic substance even though the antigenicity of other foreign substances is unimpaired, has been called an acquired tol-

The naturally occurring phenomenon was demonstrated in 1945 by Owen,81 who found that sibling cattle twins had the same blood types much more often than expected on the assumption of a random segregation of the relevant genes. This was found to be a consequence of a common, though not invariable, occurrence of a common blood supply to the twins, resulting in a natural graft of blood-forming tissue to produce a double blood type or blood type chimera. Having been implanted in the fetal organism, and thereafter continuously present, this tissue was not subsequently recognized as not-self, and an acquired tolerance, or lack of immune response to the otherwise foreign antigen, persisted after the capability of giving an immune response had developed.

The same phenomenon is demonstrable also in the response to tissue transplants, twin cattle siblings reacting to the homograft as if it were an autograft, presumably as a consequence of a "graft" in utero of epithelial tissue. The phenomenon is demonstrable experimentally by inoculating mice in utero with epithelial tissue and showing that adults of mice so treated respond to homografts as if they were autografts while untreated mice give the homograft reaction. Similarly, animals inoculated with antigens such as toxoids subsequently show a marked

impairment of ability to form antitoxin although the immune response to other antigens is not affected. The possibility of an immunological tolerance functional in persistent viral infections is a matter of some interest. 90

THE CHEMICAL BASIS OF SPECIFICITY^{19, 39, 42}

A large body of sound experimental evidence has established the fact that the specificity of antigens is determined by their chemical composition. Early experimental investigation of a wide variety of antigenic proteins has shown that immunologically identical proteins are, so far as can be determined, identical in composition; that antigenic proteins differing from one another in composition are also immunologically distinct; and that antigens showing some degree of cross-reaction are closely related in chemical structure. Conclusive evidence that immunological specificity is a property of certain atomic and molecular arrangements has been obtained through the study of altered specificity and artificial antigens.

Altered specificity. The specificity of an antigenic protein may be altered by heating, partial denaturation, treatment with formaldehyde, etc., in such a way that part of the original specificity is lost but species specificity remains although somewhat broadened. Heated rabbit serum, for instance, behaves as a foreign protein in the rabbit, and the antibodies produced will not react with unheated rabbit serum. Retention of species specificity is indicated by the fact that antibodies to the heated serum react with the homologous antigen and to only a slight degree with heated serums from other animals. Such heated proteins are known as coctoproteins. Treatment of a protein with iodine, nitric acid, or nitrous acid (the last to give the intermediate diazo compounds), on the other hand, alters the specificity of the antigen so profoundly that species specificity is largely destroyed. Nitrated rabbit serum, for example, acts as a foreign protein to the rabbit, and the antibodies developed will react not only with the homologous antigen but with nitrated protein derived from other animal species or even from plants. Since iodine, nitrate, and similar substances react with the protein by substitution in the benzene rings of the aromatic amino acids, these findings have been interpreted as indicating that species specificity is associated with aromatic radicals and their arrangement within the protein molecule, a conclusion which, as will appear, is no longer justified.

Largely through the work of Landsteiner and his colleagues in the preparation and study of a large series of artificial antigens, some aspects of the phenomenon of immunological specificity are now relatively well understood. It has been found that the species specificity of antigens may be altered in ways other than attacking the aromatic radicals. Acetylation with acetic anhydride, esterification with ethyl alcohol, and methylation with diazomethane, all changes in the salt-forming groups of the protein molecule, result in a change in specificity similar to that obtained by treatment with iodine or nitric acid. It is of particular interest that such a marked effect on specificity may be produced by the addition of the small acetyl, ethyl, or methyl groups to the large protein molecule. Even phosphorylation has been found to alter the immunological properties of egg albumin.

Artificial antigens. 42, 67 The influence of the addition of relatively simple organic radicals on the immunological specificity of antigenic proteins has been further elucidated through the study of the immunological behavior of a variety of compounds prepared from protein and the diazonium derivatives of a number of methyl, chlor, brom, and nitro substitution products of aniline and o-, m-, and p-aminobenzenesulfonic acid as well as the parent compounds, and others such as p-aminophenylarsenic acid, o-, m-, and p-aminocinnamic acid. From these and other experiments it is apparent that the immunological behavior of antigens is specifically modified by a relatively small part of the large protein molecule, and the specificity of the antigen is determined by the chemical structure of this part, cross-reactions occurring between antigens whose determinant portions are closely related aromatic groups. The spatial arrangement in the determinative groups, as well as their nature, is reflected in immunological behavior; the position, ortho, meta, or para, of substituted acid groups in the aromatic radical produces differences in specificity, the stereoisomers of tartaric

344 ANTIGENS

acid and p-aminobenzoylphenylacetic acid yield immunologically distinct antigens when coupled with protein, and the position of amino acids in peptide-azoproteins is a factor in determining immunological specificity. In the case of artificial antigens, a minimal number of determinant groups must be added to the protein moiety to alter its specificity, 10 to 20, the number depending upon the size of the molecule, but not all are functional in the combination with homologous antibody (see below).

If it be assumed that the amino acids comprising the peptide chains of the protein molecule are arranged in regular and recurring order and proportion and, consistent with present theory of protein structure, that these chains are folded, then it is apparent that the recurring combinations of amino acids in the folded chains will result in "nodes" of molecular structure and patterns of polar groups. It is supposed that this type of molecular structure confers immunological specificity on the protein molecule that is not combined with some other type of structure.

In any case, a relatively small portion of the surface of the antigen molecule serves to determine its immunological specificity. It might, therefore, be anticipated that a single molecular species of antigen might provoke the formation of more than one kind of antibody specificity, i.e., have more than one kind of determinant. There is reason to believe that this is true, at least to a limited extent. Among the naturally occurring antigens, the pneumococcal antigen includes both the polysaccharide haptenedetermined type of specificity and the species specificity of the protein moiety complexed with another carbohydrate. The former is quantitatively predominant, and early during the course of immunizing inoculations the antiserum is sharply type-

Figure 63. An example of a conjugated protein antigen prepared by coupling p-azophenyl arsenilic acid with a protein by diazotization.

specific, but on continued immunization antibody to the species-specific antigenicity becomes more and more evident. It is a general observation that hyperimmune serums are often not as sharply specific as antiserums obtained by a less prolonged course of immunization. Further, while the specificity of a protein antigen may be altered as just described, antibody may be produced to the original as well as the new specificity.

It may not be possible to distinguish multiple antigenic specificities in a presumably "pure" antigen. The differentiation of antigenic specificities by the procedures of antigenic analysis (see below) is dependent upon the independent occurrence of the component specificities. Any antigen regarded as immunologically homogeneous in that it has only a single demonstrable antigenic specificity may, in fact, have multiple specificities which occur only in this particular combination and are, therefore, not differentiable.

Haptenes. The immunological function of the haptenes; or partial or residue antigens, now becomes clear in their role as determinants of immunological specificity. The relative importance of haptene-determined specificity is very great, for a large portion of naturally occurring antigenic substances are conjugated antigens consisting of a protein moiety and a haptene, and the latter is often found in the form of residue antigen in microorganisms. The significance of haptene-determined specificity in infectious disease is illustrated in the pneumococcus, whose polysaccharide capsular substance provides the antigenic specificity required to produce an effective immunity to infection with these microorganisms.

Polysaccharides. 9 Of the residue antigens those of the pneumococcus have been the most intensively studied and for present purposes may be regarded as typical. These so-called specific soluble substances (SSS). which make up the capsule of the bacterium, have been found by Heidelberger, Avery, Goebel, and others to be polysaccharide in nature. Of the pneumococcal type-specific polysaccharides, that of type 3 has been the most thoroughly investigated and appears to be a polymer of aldobionic acid units (in this case glucose and glucuronic acid joined through a glucoside linkage, $4-\beta$ -glucuronosidoglucose, designated as cellobiuronic acid) having a molecular weight of 1000 to

5600. The nature of the other type-specific polysaccharides is not so clear. Type 2 polysaccharide hydrolyzes to glucose; type 1 is possibly a trisaccharide made up of two uronic acid (in part galacturonic acid) molecules, a third molecule containing nitrogen, and acetyl groups whose presence is of considerable immunological significance; and type 4 yields an amino sugar on hydrolysis. That such polysaccharide haptenes are not peculiar to the pneumococcus is indicated by the isolation of similar substances from a variety of microorganisms including yeasts and other fungi and certain metazoan parasites as well as many species of bacteria.

The presence of capsular polysaccharide material confers immunological specificity upon the pneumococcus types; the rough, nonencapsulated forms are species-specific, and no longer may be differentiated into types irrespective of the immunological type of the smooth, encapsulated parent form. The species specificity manifested by the rough forms, furthermore, appears to be intimately associated with the presence of yet another polysaccharide, the so-called C polysaccharide, which is common to the rough forms and which, like type 4 polysaccharide, hydrolyzes to an amino sugar but also contains phosphoric acid. The genetic transduction of pneumococcus types, then, would appear to be an alteration in the ability of the microorganism to synthesize one or another of the type-specific polysaccharides.

The immunological specificity of other bacteria, including types A, B, and C of Friedländer's bacillus, certain of the meningococcus types, staphylococci, streptococci, and other microorganisms, is similarly associated with the presence of polysaccharide haptenes. The nature of the linkage between polysaccharide and antigenic protein in the bacterial cell is not known.

It has been shown also that an effective antigen need not contain intact polysaccharide; Goebel has prepared an azoprotein antigen from horse serum and the glucoside of cellobiuronic acid whose antiserum will protect mice against type 3 pneumococcus infection. Similar protection is afforded against type 2 infection by an antiserum to an azoprotein antigen prepared from the glucoside of a *synthetic* isomeric aldobionic acid, gentio-biuronic acid (6- β -glucuronoside-glucose).

Lipids.91 Principally because of the ap-

parent solubility of Forssman antigen in organic solvents and the immunological activity of certain lipoidal preparations from tubercle bacilli, it has been thought that lipids might function either as complete antigens or as haptenes. The experimental evidence, e.g., immunization with mixtures of foreign serum and such substances as lecithin, cephalin, and cholesterol, has, however, been inconclusive, and it is therefore uncertain as yet whether or not lipids may determine the immunological specificity of antigenic proteins. A number of steroids have been found to act as haptenes when conjugated with bovine serum albumin to form a complete antigen.1

Drugs. An immune response, often manifested as a hypersensitivity, to low molecular weight substances, including antibacterial substances and other drugs as well as cutting oils and similar substances responsible for occupational dermatitis, occurs with some frequency. It is probable that the low molecular weight nonantigenic substance combines with protein of the recipient to function as a haptene and alter its specificity so that it becomes a foreign substance and antigenic to provoke an immune response. The antibody so formed reacts specifically with the drug or other substance functioning as a haptene, and allergic reactions occur. Such sensitization to penicillin, for example, is observed relatively often.

THE ANTIGENIC STRUCTURE OF MICROORGANISMS^{44, 50, 83}

The term antigen may be used loosely to mean any antigenic material or, more precisely, to mean a single antigenic substance which is immunologically pure in that it contains only a single antigenic specificity. The great majority of antigens occur in mixtures with other antigens, and microorganisms are such mixtures, containing more than one, often very many, component antigens. The microorganism, then, consists of a mosaic of independent antigens, each of which stimulates antibody formation and reacts specifically with its homologous antibody. Because of this, an antibody may be preferentially removed from an antiserum containing many kinds of antibodies by adsorption on its specific antigen to provide the basis for antigenic analysis (see below), and characterization of the microorganism by its content of differentiable antigens, *i.e.*, by its antigenic structure.

The distribution of antigens among microorganisms is analogous to that among higher forms, in that individuals, or more accurately clones, may be immunologically specific, and at the same time show cross-reactions with similar forms, but some microbial antigens are heterogenetic and occur in widely separated forms. With appropriate reservations, antigenic specificity may be taken as a measure of biological individuality among microorganisms just as in higher forms, and evidence continues to accumulate that it is genetically determined also.

Differentiation of antigens. Microbial antigens are separable into groups on the basis of chemical properties, especially resistance to heat (100° C.) denaturation, and on the basis of location in the cell structure. as well as by immunological specificity. Those associated with cell structure include the antigens present in bacterial flagella, the flagellar antigens, those present in the capsule or envelope, the capsular or envelope antigens, and those present on the cell surface proper such as certain of the typespecific antigens of the streptococci. None of these appear to be essential parts of the cell since they may be removed with no apparent effect on viability. The intracellular antigens of the cell substance proper are the so-called somatic antigens and, in some instances at least, appear to be integral parts of the cell wall. In the case of microorganisms containing endotoxins, the toxicity is intimately associated with antigenicity, and endotoxin and somatic antigen may be wholly or in part identical. In addition to these kinds of antigens, soluble antigenic substances secreted by the microbial cell, such as exotoxins, various toxic activities such as hemotoxins and cytotoxins, and enzyme or enzyme-like activities such as kinases, are used also in the immunological characterization of microorganisms.

Some of the variety of antigens that may be present have been alluded to earlier. The capsular antigens, which are usually polysaccharides, but may be polypeptides, have been described above in connection with haptene-determined specificity. The myosin-like flagellar protein, flagellin (Chap. Three), includes the heat- and alcohollabile H antigens, so-called because their presence in enteric forms is associated with motility and a spreading (Hauch) type of growth on agar mediums. The somatic antigens of the enteric bacilli are the lipidpolysaccharide-polypeptide complexes that are the endotoxins, or lipopolysaccharides (Chap. Nine), and they are called O antigens because they are present when the microorganism is nonmotile and growth on agar mediums is not spreading (ohne Hauch). The antigenic specificity of the somatic antigens is a function of the polysaccharide moiety.46,74 The exotoxins and other toxic activities have also been described elsewhere (Chap. Nine).

Characterization. The immunological characterization of a microorganism may be relatively simple, in that one or two antigens may suffice for differentiation, or complex and concerned with many antigens. The diphtheria bacillus is an example of simple practical differentiation and is identified by its production of immunologically specific diphtheria toxin, and other characteristics are peripheral to this one. The pneumococcus is somewhat more complex, for two kinds of antigens are involved, that of the cell substance proper and that of the typespecific capsular substance. Differentiation of streptococci makes use of four kinds of antigens, a polysaccharide group-specific antigen and at least three type-specific antigens of polysaccharide, protein, and nucleoprotein nature. The antigenic structure of the enteric bacilli is more complex. In the Salmonella group the antigens are separable into the flagellar or H antigens, and the somatic or O antigens, with the former subdivided into phase 1 and phase 2 flagellar antigens. The somatic antigens were arbitrarily numbered by Roman numerals (Arabic numbers are beginning to be used), and the flagellar antigens by Arabic numerals and by lower case letters. Using these symbols, the antigenic mosaic of a bacterium of this group may be given as an antigenic formula; the paratyphoid B bacillus, for instance, has the formula I, IV, V, XII: b - 1,2. The coliform bacilli are equally complex antigenically, containing in addition to H and O antigens, somatic surface or envelope antigens called K antigens, and the K antigens are subdivided into L, A, and B groups of antigens. The antigenic characterization of these and other microorganisms is considANTIBODIES 347

ered in subsequent chapters devoted to more detailed consideration of individual microorganisms.

Common antigens. The heterogenetic antigens of microorganisms are usually called common antigens, i.e., common to more than one kind of organism. The Forssman antigen is one of these and is found in some bacteria, but not others, as well as in higher forms as indicated earlier. Other common antigens are shared by microorganisms with other forms, such as the immunological relationship between type 14 pneumococcal polysaccharide and the human blood group A substance; and those of type 2 pneumococcus, type B Friedländer's bacillus, and other coliforms to certain species of yeasts and vegetable gums such as gum acacia. Other common antigens occur between microorganisms as widely separated as the cholera vibrio and Brucella and the plague bacillus and paratyphoid B bacillus. There are many such examples, and it is clear that certain antigenic specificities found in microorganisms are heterogenetic in the sense that they seem to occur at random.

Antigenic variation. The antigenic character of microorganisms is subject to variation (Chap. Seven), and this may be viewed as variability in the ability to synthesize antigenically specific substances. In bacterial variation of the S-R type followed immunologically, the microorganism may be successively "degraded" with the disappearance of antigens and the appearance of apparently "new" antigens. This has been taken by some as indicative of the occurrence of antigens in layers like the layers on an onion which may be peeled off in successive degradations to expose new antigens. With the exception of flagellar and capsular antigens, there is no substantiation for such a view. It is more probable that the effect is one of alteration in the ability of the microorganism to synthesize haptenes, and when it fails to produce a haptene, such as a carbohydrate, the antigenic specificity of the protein moiety appears as a new antigen, or a new antigen occurs as a consequence of synthesis of an altered haptene to give a different antigenic specificity to the conjugated antigen.

Antibodies78, 79

The immunological response of an animal to the initial injection of an antigenic substance is not immediate but, after a suitable time interval or incubation period, is manifested as an alteration in the properties of the blood serum with respect to the antigen. An immune serum, or antiserum, differs from normal serum in that it reacts, either in vivo or in vitro, with the homologous antigen. This property of immune serum is a consequence of the presence of antibodies, substances which are formed by the animal body in response to the presence of antigen in the tissues and which combine specifically with the antigen. Since antibody is found in largest amount and in most convenient form in the blood serum, the properties and nature of antibody may be considered in terms of serum antibody.

Nature of antibody. Antibody activity is intimately associated with serum protein, and antiserums may contain 1 to 5 mg. per milliliter or even more antibody protein. In general, the activity is localized in the globulin fraction of the serum protein, the first to be precipitated by sodium or ammonium

sulfate or ethanol in the cold, but usually the concentration range over which precipitation occurs is not sharp. When serum globulin is salted out, as by half-saturation with ammonium sulfate, all of the antibody activity is precipitated and occurs in both the euglobulin and pseudoglobulin fractions, and usually less than 50 per cent of the total globulin, even in a hyperimmune serum, is antibody of a given specificity.

On electrophoretic fractionation of serum protein, the globulin is separable into three fractions on the basis of mobility: α -globulin. β -globulin, and γ -globulin in order of decreasing mobility. Antibody activity occurs almost exclusively in the y-globulin fraction, but there are occasional exceptions in which the several antibodies produced in response to inoculation with a complex antigen may be segregated in different protein fractions. For example, in the guinea pig sensitized with tubercle bacilli, antibody to the tuberculopolysaccharide is contained in the y-globulin fraction, while that to tuberculoprotein is found in the α -globulin and even to a certain extent in the albumin fraction. 17

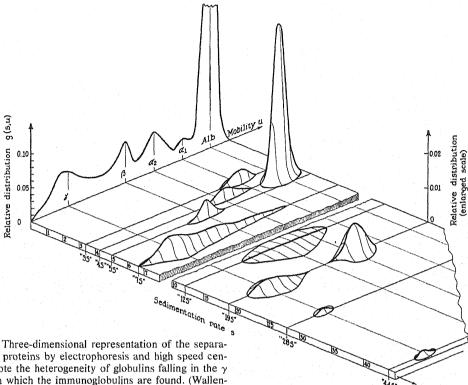

Figure 64. Three-dimensional representation of the separation of serum proteins by electrophoresis and high speed centrifugation. Note the heterogeneity of globulins falling in the y and β areas in which the immunoglobulins are found. (Wallenius: J. Biol. Chem.)

Or antibodies to the antigenic complex of the sheep erythrocyte which occur in the γ -globulin fraction may be found in separable parts of that fraction. Such variation in the distribution of antibody activity may be related to certain observed differences in the stability of antibody to different antigens. For instance, preservation of H-O antiserums with 0.5 per cent phenol is undesirable because on storage there is a preferential reduction and even eventual disappearance of antibody to the O antigen. Similarly, the antibody to O antigen is markedly reduced by heating to 70° C., while that to H antigen is not.52

In general it has not been possible to separate antibody activity from serum globulin, using a variety of purification procedures (see below). Thus, diphtheria antitoxin has been prepared as a pure protein crystallizing in thin plates and containing 700,000 to 1,000,000 antitoxic units per gram, and evidence such as this has led to the inevitable conclusion that antibody is modified serum globulin.

Immunoglobulins. 16, 23 Antibody activity is a property of more than one molecular species, which are separable by various

physical methods including electrophoresis, osmotic pressures, diffusion rates, viscosity, sedimentation by high speed centrifugation, and, more recently, immunoelectrophoresis (Chap. Fourteen), and are designated immunoglobulins. Two species have long been known, 7 S immunoglobulin having a molecular weight of about 150,000 or "classic" antibody; and 19 S immunoglobulin, or macroglobulin, having a molecular weight of about 1,000,000. The latter was originally described as formed by horses, pigs, and cattle in response to pneumococcus, though these animals form 7 S antibody to other antigens. It is now clear that 19 S antibody is not at all uncommon, and generally is formed early in the course of the immune response, while 7 S antibody is formed later.

The application of immunoelectrophoretic analysis to allow the separation of serum proteins of differing antigenic specificity and mobility has resulted in the differentiation of many serum proteins, including additional immunoglobulins. The terminology applied to the immunoglobulins has tended to become confusing, and an international nomenclature has been suggested under the auspices of the World Health Organization⁶³

which is gaining general acceptance. In this nomenclature, 7 S antibody, which has also had other designations, is termed IgG or γ G, the Ig or γ referring to immunoglobulin, and 19 S, or macroglobulin, is IgM or γ M. A third immunoglobulin, IgA, initially separated by immunoelectrophoresis and having a molecular weight of about 150,000, has been found in human and rabbit serum. A fourth, IgD, appears to occur in man and possibly also in the rabbit, but in very small amount and of doubtful antibody activity. The terminology of the three main classes of immunoglobulins is summarized in the accompanying table.

Properties of immunoglobulins. Analytical evidence indicates that the immunoglobulin molecule consists of four peptide chains, two heavy or long chains, and two light or short chains, joined by disulfide bonds. Certain biological properties suggest that the light chains may be double, and the molecule made up of six rather than four peptide chains, but the four-chain structure illustrated in the accompanying diagram is presently generally accepted as representing the basic structure of IgG. The heavy chains, also called A or H chains, have a molecular weight in IgG of about 50,000, are associated with the carbohydrate portion of the molecule, differ in amino acid content, and determine the distinctive properties of each class of immunoglobulin. The light, or B or L, chains have a molecular weight of about 20,000, occur in two electrophoretic mobilities, and are the subunits common to the three major classes of immunoglobulin.

The molecular weight of IgG agrees well with the sum of the molecular weights of its components. IgA has the same general structure, but the heavy chains have somewhat greater molecular weights, 60,000 to 100,000. IgM is considered to be a polymer of five basic four-chain structures in which the heavy chains have a molecular weight

of 65,000 to 70,000. Hydrodynamic data indicate that the IgG molecule is elongated, 250 to 300×40 Å, with an axial ratio of about 8; the IgM molecule is about the same diameter but longer. The prototype of the large antibody molecule is the Waldenström macroglobulin.

DEGRADATION. The structure of the immunoglobulins is inferred from study of degradation products of reduction with thiols, and digestion with papain or pepsin. Reduction splits sulfide bonds, and gentle reduction the interchain linkages, of which that linking the heavy chains is the most labile. Cleavage of the linkage between the heavy chains only gives two fragments, each made up of one light chain and one heavy chain, which retain antibody activity but behave as if they were monovalent; i.e., they will combine with antigen but lattices (see below) are not formed.

Enzymatic digestion splits the molecule across the heavy chains, leaving the disulfide bond between them intact. Cleavage by papain is at a point between the bond linking the heavy chains and those linking the heavy chains to the light chains. The molecule is, therefore, split into approximate thirds, giving two fragments containing a light chain and a portion of a heavy chain. and one fragment consisting of parts of two heavy chains and their associated carbohydrate linked by a disulfide bond, which is readily prepared in crystalline form. The light chain-heavy chain fragments are designated papain pieces I and II, and the other fragment papain piece III. Pieces I and II retain antibody activity but are monovalent, and piece III is immunologically inactive. These and other fragments of the immunoglobulin molecule are designated by the letter F: pieces I and II which have antibody activity are Fab, and the third fragment is Fc. Reduction of Fab with thiols splits the disulfide bond linking the light

Classes of Immunoglobulins

STANDARD (WHO	0)	OLD TERMINOLOGY	MOLECULAR WEIGHT	HEAVY CHAIN DESIGNATION
IgG or γG	**************************************	γ , 7 S γ , 6.6 S γ , γ_2 , γ_{ss}	150,000	γ
IgA or γA		$\beta_2 A, \gamma_1 A$	150,000	$oldsymbol{lpha}$
IgM or γM		$\gamma_1 M$, $\beta_2 M$, 19 Sy, γ -macroglobulin	1,000,000	μ

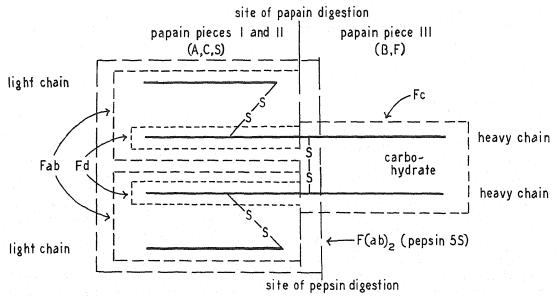

Figure 65. Diagrammatic representation of the presently accepted structure of the immunoglobulin (IgG) molecule. The antibody-combining sites are probably not adjacent as here indicated. (After Porter.)

chain and the portion of the heavy chain, with disappearance of antibody activity, and the heavy chain fragment is Fd.

Peptic digestion at pH 5 splits the immunoglobulin molecule on the other side of the disulfide bond linking the heavy chains to give a large fragment of about 100,000 molecular weight, the 5 S fragment, which has full antibody activity and, in the above notation, is F(ab')₂. The remainder of the molecule is accounted for as small fragments with no antibody activity. F(ab')₂ may be split by gentle thiol reduction of the disulfide bond linking the heavy chain portion of the complex to two components corresponding to Fab and retaining monovalent antibody activity.

Papain pieces I and II are separable by differences in electrophoretic mobility at neutrality into two types with respect to the light chain component. That of higher mobility is piece I from rabbit IgG and A in human and other serums, and that of lower mobility is piece II in the rabbit and C in the serum of other species. There are, then, two types of each class of immunoglobulin, designated K and L. As indicated above, the heavy chains are distinctive for each class. In the WHO nomenclature for molecular formulae, K and L light chains are κ and λ , and the heavy chains of the classes IgG, IgA, and IgM are γ , α , and μ respectively. On this basis molecular formulae can be written, that of IgG, for example, is $\gamma_2 \kappa_2$ or $\gamma_2 \lambda_2$ as the case may be; other designations and formulae are shown in the accompanying table.

BIOLOGICAL ACTIVITY. The biological activity of immunoglobulins is of two general kinds: their antigenic and their antibody activity. Regarding the former, the short chains are common to the known species of immunoglobulin, while the long chains are antigenically specific and differentiate the classes from one another. This is demonstrable by reacting papain fragments with specific antiserums; e.g., antiserum to light chain antigen will react with pieces I and II, but not with piece III, while antiserum to heavy chain antigen reacts with pieces I, II, and III and is class-specific, as well as giving cross-reactions between classes. The long chain antigens, then, con-

Immunoglobulin Formulae

PRESENT USAGE	ABBREVIATED NOTATION	MOLECULAR FORMULA	
7 Sy = type I	IgGK or yGK	$\gamma_2 \kappa_2$	
7 Sy = type II	IgGL or yGL	$\gamma_2\lambda_2$	
$\gamma_1 A = \text{type I}$	IgAK or yAK	$\alpha_2 \kappa_2$	
$\gamma_1 A = \text{type II}$	IgAL or vAL	α,λ,

$\gamma_1 M = \text{type II}$	IgML or yML	$[\mu_2\lambda_2]_5$	

tain both group and individual specific antigens. The contained carbohydrate does not appear to determine antigenic specificities. The heavy chain antigens are isophile antigens, and considerable interest has attached to their genetics.⁶⁴

All three classes of immunoglobulin have full antibody activity. As noted earlier, IgM is usually the first to appear during the course of immunization and is eventually replaced by IgG. The time course of IgA is not altogether clear, but it seems to follow IgM and may coexist with IgG. The classes differ in their functional antigenicity. In general, the early, but transient, IgM reacts well with particulate antigens such as bacteria, but poorly with soluble antigens such as toxins, while IgG is more effective as, for example, antitoxin, and appears to be concerned in the anamnestic reaction, i.e., in immunological memory, but IgM is not. It has been suggested that IgM represents a rapidly mobilized first line of immunological defense against bacterial infections. Antibody functional in hypersensitivities, e.g., reagin, appears to be wholly IgA.

IgG has been described as preferentially transmitted across the placental barrier, but immunoglobulin present in secretions such as tears, saliva, respiratory and intestinal mucus, and colostrum and milk, and known as secretory immunoglobulin, appears to be largely, if not entirely, IgA. Serum IgA, as described above, tends to be somewhat variable in sedimentation rate, possibly tending to form aggregates, but secretory IgA is homogeneous in this respect. Further, it contains an additional peptide chain, designated the T-chain, which appears not to be covalently linked with the remainder of the molecule. This "secretory piece" is considered by some to stabilize the antibody. The IgA present in secretions appears to be locally formed, at least in the case of that present in intestinal mucus. It is demonstrable in the antibody-forming cells of the lamina propria (Chap. Fifteen) by the use of anti-IgA antibody, often as fluorescent antibody staining (Chap. Fourteen), and has been shown to occur in the mucosal epithelial cells in the large bowel, suggesting a transepithelial pathway into the lumen of the bowel.24

It is apparent from consideration of the structure of the immunoglobulin molecule and the antibody activity of its fragments that (a) both light and heavy chains participate in the reaction with antibody and (b) that there are two antibody combining sites on IgG. Since IgM is a polymer of five such units, it might be supposed that it would have 10 combining sites, but this is not true for it is also divalent. The site of antibody activity at a point involving both light and heavy chains has been further substantiated by Singer through the development and application of the technique of affinity labeling. ⁶⁹

Antibody synthesis.^{75, 86} The outstanding differential characteristic of immune globulin is its property of reacting specifically with homologous antigen. Modification of normal serum globulin is such that this property is acquired, but the modification is of a sufficiently subtle nature that it is not detectable by the usual analytical methods.

It will be recalled that the basis of antigenic specificity is the chemical nature and configuration of a haptene or other small determinant portion of the antigen molecule. It may be taken to follow that the modification of serum globulin which gives it antibody activity can be inferred from the nature of antigenic specificity. The antigen-antibody complex formed when the two react with one another is held together by secondary valencies (see below) which are probably dependent upon the occurrence of one or more areas upon the surface of the antibody molecule in which the pattern of polar forces is a kind of mirror image of that determining antigenic specificity. There is no evidence that such an area is attached to the otherwise normal serum globulin. On the contrary, it seems to be built into the structure of the molecule, resulting, according to Pauling, from the way in which the peptide chain is folded, and the localized pattern of polar forces occurs in the same way as that determining the antigenic specificity of a pure, unconjugated protein. After folding has been completed, the configuration is stabilized by the insertion of -S-S- and hydrogen bonds.

Theories of antibody formation.^{7, 13} In a very real sense, in the stimulation of antibody formation, the presence of antigen acts as an inducer of the synthesis of immune globulin in a manner analogous to the function of the inducer of adaptive enzyme formation (Chap. Seven). The specificity of the product of such induced synthesis is

attributable to the template provided by the determinant portions of the antigen molecule. The most widely accepted theory of antibody formation was suggested by Breinl and Haurowitz and by Mudd at about the same time (1930-1931). According to this theory, antigen, and more recent evidence suggests an antigenic fragment, persists for extended periods in the antibody-forming cells (Chap. Fifteen) to provide the template against which specific antibody is formed.¹⁴ The striking analogy to the induction of adaptive enzyme formation has been extended in an attractively plausible theory of antibody formation by Burnet¹⁰ in which the initial antigenic stimulus functions as an inducer, and the enzymatic adaptation giving altered, or immune, globulin persists for an extended period after the inducer, or antigen, has disappeared.

The foregoing is known as the "instruction" kind of theory; i.e., the antigenic stimulus, whether it be a fragment of an antigen or derived from an antigen, is external to the genone of the antibody-forming cell. A second kind of theory, the "selection" theory, was proposed by Jerne³⁶ in 1955, and has been elaborated by Burnet and others. 11, 43 In this kind of theory the pre-existence of individual antibody-forming cells (Chap. Fifteen) which, in the aggregate, can synthesize all possible immune globulins, is assumed. The antigenic stimulus, then, results in the preferential proliferation of those having the immunological potentiality to react with the antigen. Because of the selective effect of the antigenic stimulus. this kind of theory has been called the "clonal selection" theory. It may be considered to be a sophisticated version of the classic side-chain theory of Ehrlich (see below). The obvious objection to it is the necessity for postulating the appropriate, and essential, random somatic mutations of mesenchymal cells, presumably during the course of embryonic development, to give clones of the required specific immunological potentialities.

A highly provocative theory has been advanced by Smithies⁷² based on analogy with viral replication. It is suggested that, since the synthesis of immune globulin is in all probability nucleic acid-directed, such altered nucleic acid may be transferred to potential antibody-forming cells, and that such immunological competence per-

sists through replication of such altered cells.

It is not yet possible to assay the validity of these various theories of antibody formation, but the generalities are not mutually exclusive and they may well be combined in time. The sites of antibody formation, the persistence of antigen in the cells and tissues, and similar factors are significant elements (see Chap. Fifteen).

Rate of formation. However this may be, the formation of antibody is, in large part if not entirely, a total synthesis as indicated by the extremely rapid incorporation of labeled amino acids from the amino acid pool, with a transit time of 40 minutes at the most, and possibly considerably less. during the stage of active antibody formation. The rate of formation of antibody is deduced from serum antibody titer after correcting for the catabolism of antibody already present whose half-life ranges from two to five days. It is usually more rapidly destroyed in smaller animals having higher metabolic rates, but exception is to be noted in the case of the human infant in which antibody persists as long or longer than in the adult in spite of a relatively higher rate of metabolism.

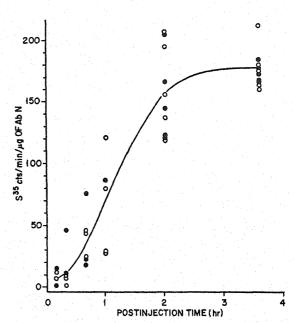

Figure 66. The rapid total synthesis of anti-bovine serum albumin antibody by the rabbit is shown by the rate of incorporation of S³⁵-labeled amino acids into the antibody molecule. (Taliaferro and Taliaferro.)

Antibody appears in the serum of the inoculated animal only after a latent period, rises rapidly and almost exponentially and falls off somewhat before reaching a peak. and then declines relatively slowly, the time dimension of the response varying with the antigen (Chap. Fifteen). This is the primary immune response. The latent period is regarded by some as the time required for the metabolism of the antigen, possibly to fragments which are the immediate inducers of antibody formation, and by others as a period during which a precursor is formed which subsequently reacts with antigen and is converted to antibody, and there is no doubt that a part of the latent period is required to saturate the tissues with antibody prior to the spilling over of the excess into the blood stream.

Secondary response. The secondary response is given by an animal having had a prior inoculation of the antigen, even months ago, and is characterized by a greatly reduced time required to reach peak serum titer - in the case of toxoids the time is reduced from two to four weeks to a few days—and the peak titer is often considerably higher than that reached following primary inoculation. It is obvious that the effects of the initial antigenic stimulus persist as a hyper-reactivity of the antibodyforming mechanism to the antigen, and it is for this reason that the secondary response is called the anamnestic, or remembering, reaction. The occurrence of the anamnestic reaction presents some difficulties for theories of antibody formation; in the adaptive

enzyme theory, for example, the adaptive enzymes catalyzing the synthesis of immune globulin are assumed to be self-duplicating under the second antigenic stimulus.

As indicated above, Pauling⁵⁵ has suggested that actual modification of the serum globulin occurs late in the process of synthesis, after synthesis of peptide chains is partially or largely complete. There is a certain amount of evidence for this in that it has been possible to denature, or unfold, normal globulin slowly by heating gradually to 57° C. and holding at this temperature for about two weeks in the presence of 2,4,6tri(p-azophenylarsonic acid) benzene as an "antigen," and cooling slowly to renature the globulin; the renatured globulin gave some antibody-like reactions but cannot be called antibody.56 The development of specificity as late as this in globulin synthesis is not consistent with the total, or practically total, synthesis of immune globulin from the amino acid pool. In this connection it may be pointed out that there is no evidence that normal globulin is a precursor of immune globulin, although labeled amino acids may be recycled from catabolized normal globulin and subsequently appear in immune globulin; nor is there any substantiation for the older idea that antigen is actually incorporated in the antibody molecule.

However the reactive sites are formed during the synthesis of immune globulin, there are only one or two, and probably not more than three, such areas on the surface of the molecule that are functional in that they will combine with antigen although

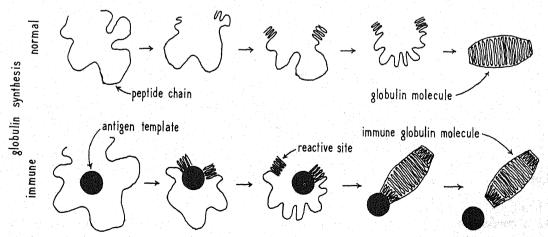

Figure 67. Diagrammatic representation of the sequence of events assumed to occur if antibody activity results from a directed folding of the peptide chain during synthesis. (After Pauling.)

354 ANTIBODIES

others may be present internally. It has been calculated that each combining site occupies a relatively small part, 1 per cent or less, of the total surface of the immune globulin molecule, and it is obvious that only a small portion of the molecule is directly concerned in the reaction with antigen. The number of such combining sites is spoken of as the valence of antibody, and, in general, antibody is monovalent or divalent in contrast with antigen which is multivalent (see below). When the antibody molecule is illustrated in diagrammatic form, the two reactive sites are usually shown at either end of the elongated molecule, but there is no reason to suppose that they occur in these positions or are even symmetrically placed.

Since the modification of globulin giving it antibody activity consists of the presence of "abnormal" localized patterns of polar forces on the surface of the molecule, it might be supposed that these areas may function as haptenes to alter the specificity of globulin as an antigen. If so, immune globulin might be antigenic in the animal producing it, and it should be possible to obtain antibody to antibody by immunization of other animals. This has not proved to be true, possibly because even if such reaction sites can function as haptenes, there are too few to alter the antigenic specificity of the globulin molecule.

Heterogeneity of antibody.^{22,89} At one time it was assumed that the several antibody activities demonstrable in the various serological reactions (Chap. Fourteen) are those of separate and distinct antibodies, that for example antitoxic and precipitating

antibodies to the same antigen are different, a supposition apparently supported by discrepancies in antibody titer measured in different ways. On the other hand, the essential similarities between certain of the serological reactions, especially precipitation and agglutination, are apparent and are reinforced by observations such as the passive agglutination of particles coated with soluble antigen by precipitating antiserum and the precipitating as well as antitoxic activity of antibody to exotoxins.

The common factor in the serological reactions, and in in vivo titrations of antibody activity, is the union of antigen and antibody (see below), but the consequences of that union are variable and determined by the way in which the test is carried out; e.g., is the antigen precipitated, is the animal protected against the toxin, etc.? Largely for physical reasons, some kinds of serological reactions require more antibody than others, thus leading to apparent differences in the amount of antibody determined. When it became generally clear that such discrepancies are, in fact, artifacts, the homogeneity of antibody to a single, immunologically pure antigen was formalized as the unitarian hypothesis. This simply states that a single antibody can produce various consequences following its union with antigen, and the different consequences observed are not evidence of the presence of more than one kind of antibody.

While this generalization holds true, it is equally clear that antibody is, in fact, heterogeneous, but in a different sense. Two kinds of heterogeneity are to be distinguished. The first is spurious in the sense

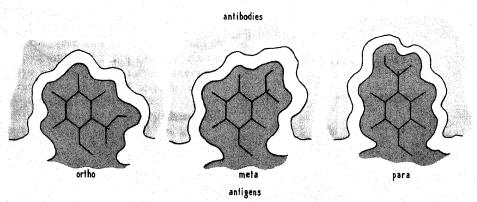

Figure 68. Diagrammatic representation of the effect of optical isomerism on antigenic specificity and the relation of the haptene to the site of antibody activity on the surface of the antibody molecule. (After Pauling.)

that the term antigen is often used collectively. While an immunizing preparation such as typhoid vaccine is called an antigen. it is in fact a mixture of the individual antigenic components of the mosaic making up the antigenic structure of the microorganism. Or the sheep erythrocyte, which contains Forssman antigen together with several isophile antigens, is also a mixture of antigens. When an animal is immunized with such material, the immune response is multiple, a group of differentiable antibodies, each specific for one antigenic component. are produced, and the antiserum is obviously heterogeneous with respect to its antibody content.

This may assume considerable practical importance. In the first example noted above, antibody to the H antigenic complex of the typhoid bacillus is not protective and is unrelated to immunity to the disease, while the antibody to the O antigenic complex is protective and the basis of an effective immunity. Since the titer of agglutinating antibody to the H complex is commonly much higher than that to the O complex. assay of the immune response by agglutination of the typhoid bacillus by the antiserum does not accurately measure immunity to the disease. In the second example, the titration of antibody that will sensitize the red cell antigen to lysis by complement (Chap. Fourteen) does not measure a single antibody, but rather the hemolytic antibody that happens to be present in highest titer.

Even when antibody is seemingly not heterogeneous in this respect, in that its formation is provoked by an immunologically "pure" antigen having but a single known specificity, more than one kind of antibody specificity, and therefore more than one kind of antibody, may be present in such an immune serum. It was noted earlier in connection with antigenic specificity that a single molecular species of antigen may have more than one demonstrable specificity and that what appears to be a single specificity may, in fact, be a complex antigen whose several specificities have not been found to occur independent of one another. Thus antibody to what is considered to be a single antigenic specificity may be heterogeneous, and the antiserum contains several antibodies specific for different parts of the antigen molecule. It is theoretically possible that such multiplicity may contribute to apparent differences in avidity of antibody (see below).

The second kind of heterogeneity is that of antibody to a single antigenic specificity. That some such variability occurs is already apparent from the earlier discussion of the properties of antibody. Antibody activity occurs in differentiable protein fractions such as IgM, IgA, and IgG, and antibody function becomes more efficient in time, with differences as much as 10,000-fold in combining power between early and late IgG; *i.e.*, there is a progressive change in the quality of the antibody.

Incomplete antibody.33 There is also a heterogeneity in antibody activity itself that may be divided into two kinds. The one is concerned with the number of reactive sites present on the immune globulin molecule. It was noted above that there may be one or two of these, and possibly rarely as many as three. Disregarding the last, antibody may, then, be monovalent or divalent (also see below). The former does not give the usual serological reactions and is demonstrable indirectly by its inhibiting or blocking effect on the reaction of antigen with divalent antibody and is also known as nonprecipitating, incomplete, or blocking antibody.

Truly monovalent antibody may be prepared by thiol reduction as indicated above. Unless the active fragments, Fab, are stabilized they will readily combine to form divalent antibody. Such combination may occur between Fab's of different specificity. For example, suppose two parent immunoglobulins having specificities AA and BB are reduced and allowed to combine. It is apparent that the combination occurs at random, since divalent molecules of specificities AA, BB, and AB are produced in the ratio of 1:1:2. Or immunoglobulin may be mixed with normal globulin, split, and allowed to combine to give monovalent antibody of the original molecular weight of the hybrid. There are some discrepancies between such monovalent antibody and naturally occurring blocking antibody, and it is not clear to what extent the naturally occurring blocking antibody can be considered to be monovalent in a strict sense.

Avidity. The other kind of heterogeneity in antibody activity is a consequence of how well or how poorly the reactive sites on the surface of the immune globulin mole-

cule are developed. The forces that bind antigen to antibody in the antigen-antibody complex are individually weak but in the aggregate provided a firm though dissociable union. When the reactive site of the antibody corresponds precisely to the determinant portion of the antigen, the maximum number of weak forces are operative, the complex is firmly bound, and the antibody is said to be highly avid. When the site is imperfectly developed, the complex is more readily dissociated, occasionally to such a degree that antigen and antibody may coexist in the same solution with only a small portion combined as the complex, and such antibody has a low avidity. Differences between IgM and IgG, and the increasing efficiency of the antibody activity of the latter, have been noted above. Antibody is, then, heterogeneous in this respect, and antibodies of varying degrees of avidity are found in the same antiserum.

Purification of antibody. The purification of antibody is a matter of its separation from other serum proteins, and the methods used are of two general kinds: the nonspecific chemical or physical methods and the specific methods which make use of homologous antigen.

The nonspecific methods commonly used are the precipitation of serum globulin by salting out, usually with ammonium sulfate, or by ethanol in the cold, and by electrophoretic methods. Serum globulin is precipitated at half-saturation with ammonium sulfate, achieved by the addition of an equal volume of the saturated solution to the antiserum, and adjusting to pH 7.8. The precipitate is washed, redissolved, and the ammonium sulfate removed by dialysis. Variations of this method are used commercially to effect a partial purification of antitoxins, and preparations of this kind may be given labels such as "immune globulin solution." Immune globulin is also precipitated by ethanol. A 1:1 dilution of the antiserum is chilled to 0° C. and 50 per cent ethanol added in small increments over a period of several hours until the final concentration is 20 per cent by volume. The temperature is lowered to -5° C., and after precipitation is complete, the precipitate is removed by centrifugation and dissolved in isotonic saline. Preparations of this general nature are often called "gamma globulin." The immunoglobulin species described above may also be separated from an immune serum for the study of biological, as well as physical, properties. Although they are differentiable by immunoelectrophoresis, column electrophoresis is not a satisfactory preparatory method, and IgM and IgA are not readily separated by centrifugation. The most commonly used procedure is fractionation by ion exchange chromatography. Nonspecific methods such as these separate the antibody-containing protein fraction of immune serum, but at best less than half of such preparations consist of antibody.

The specific methods of purification of antibody consist of reacting the antibody with homologous antigen to give an insoluble antigen-antibody complex which, washing, is dissociated to give free antibody. This approach is usually practical only when the antigen is, or can be made, insoluble so that it may be removed from the mixture after dissociation. Bacteria are, of course, particulate antigens and, after combination with antibody at neutrality, the complex is dissociated at pH 3, and the bacterial antigen removed by centrifugation to leave purified antibody in solution. Soluble antigens present a more difficult problem and a number of methods have been devised. Perhaps the simplest is the adsorption of antigen on ion-exchange cellulose. Antibody is specifically removed by combination with antigen on percolation through a column, and then preferentially eluted. Or the antigen may be thiolated, and the antibody separated from the antigen-antibody precipitate by removal of the thiolated antigen.⁷⁰

The Antigen-Antibody Reaction 48, 53, 88

The nature of the reaction between antigen and antibody has been of great interest since the phenomenon was originally described. The first comprehensive theoretical formulation was that of Ehrlich in 1906. He made the basic assumption that specific local reactive sites or receptors for food substances and also for antigens are pre-existing

on the body cells or cell structures. These receptors were regarded as having a relation to the cell structure analogous to that of side chains of complex molecules to the molecular nucleus, and this theory is known as Ehrlich's receptor theory or side-chain theory. According to this theory, when the receptors are saturated with antigen, particularly toxic antigen, the cell responds by synthesizing receptor substance in excess which then occurs free and is antibody. In order to account for the various manifestations of antigen-antibody union in the serological reactions, three kinds of receptors, of increasing complexity and designated as of the first, second and third orders, were postulated.

The combination between free receptors, or antibody, and antigen was considered by Ehrlich to be analogous to the neutralization of a strong acid by a strong base, and deviations from behavior predicted on this basis were accounted for by postulating varying degrees of avidity of antibody. This theory was slightly modified by Arrhenius in assuming that the antigen-antibody reaction is analogous to the neutralization of a weak acid by a weak base, so accounting for discrepancies such as dissociation of the antigen-antibody complex. These theories have little more than historical interest, but certain of the concepts and terminology, such as the term receptor, persist with modified meaning.

A more precise understanding of the nature of the antigen-antibody reaction began with Bordet's insistence in 1920 that it be considered as an adsorption phenomenon, and developed from the elucidation of the chemical basis of specificity described above and from the use of quantitative methods in the study of the reaction.

The antigen-antibody reaction may be differentiated into two stages, a primary stage concerned with the actual union, which occurs very rapidly, and a secondary stage which evolves more slowly as a consequence of that union. Here the primary stage will be considered, and the various manifestations of the secondary stage in the following chapter as the serological reactions. The secondary stage may be of such a nature that it is somewhat removed from the primary stage, but in the specific precipitation of antigen and antibody in the precipitin reaction, the precipitation is a direct exten-

sion of the primary reaction in that the antigen-antibody complex forms aggregates which appear as a visible precipitate. This reaction has been used almost exclusively in study of the antigen-antibody reaction, and for present purposes it is necessary to anticipate this serological reaction here.

Specificity. The nature of the specificity of the union between antigen and antibody and its surface, or adsorptive, character is indicated by the nature of antigenic, and by inference antibody, specificity as described above. It is dependent upon the juxtaposition and orientation of the haptenic or other determinant of specificity of the antigen with the reaction site on the immune globulin molecule. The antigenic determinant is visualized, at least in the case of artificial conjugated antigens, as projecting from the surface of the protein moiety, and it is believed by some that the corresponding reaction site on the homologous antibody may be in part a crypt in the surface of the globulin molecule; e.g., the shape of the haptene structure is important as well as its constituent atoms. The specificity of the union, then, involves orientation in at least two planes, and possibly also in three; and if the latter holds true, the specificity of the union is analogous to that operative in the formation of mixed crystals.

Intermolecular forces.⁵⁷ When the reaction sites of antigen and antibody have been brought into juxtaposition, they are specifically adsorbed to one another and held together by secondary valencies. These are not covalent bonds, but include electrostatic attraction between oppositely charged groups, dipolar interaction between polar but undissociated groups, hydrogen bonds, and van der Waals forces. None of these are strong bonds, and the last is the weakest, but when the stereochemical configurations of the bound molecule and receptor site are in juxtaposition, they are operative and form a firm, but dissociable, union. Of these, the coulomb forces between oppositely charged groups are possibly the most important as indicated by the marked effect of polar groups on specificity and the relatively high heat of the primary antigenantibody reaction.

Valence. The valence of antigen or antibody refers to a reaction site, the determinant or haptenic group of the former and the receptor site of the latter. It has been

implied earlier that antigen is multivalent in that a number of haptenic groups, such as arsenilic acid, must be attached to the protein moiety to alter its antigenic specificity. The number that are so attached to a pure protein of known molecular weight may be determined by analysis for, for instance, arsenic in the case of arsenilic acid conjugates. The number of such groups that are functional in the union with antibody may be shown by analysis of the antigen-antibody complex to be a function of the size of the antigen molecule. For example, the functional valence of ovalbumin having a molecular weight of about 40,000 is 5 or 6-i.e.this number of molecules of immune globulin may be attached to it when antigen is in excess-that of diphtheria toxin of molecular weight of about 70,000 is 8, and that of the high molecular weight (650,000) thyroglobulin is about 40. These are minimal values and represent the number of reaction sites that can unite with antibody simultaneously for antibody cannot react with sites too close together because of steric hindrance.

While complete antigens are multivalent. simple haptenes such as arsenilic acid are monovalent, and complex haptenes are multivalent. This is the basis for subdivision of haptenes into two groups as noted earlier. Monovalent haptenes will react with antibody, but complexes are not formed (see below), and the union is demonstrable indirectly by showing that the reacted antibody will no longer react with multivalent antigen. Haptenes may be made divalent by combining, for example, two arsenilic acid groups with some other compound, such as a dye, and such divalent haptenes give antigen-antibody aggregates. Most of the naturally occurring haptenes, such as polysaccharides, are multivalent and react with antibody to form aggregates even though they may not stimulate antibody formation.

It has been pointed out earlier that antibody may be monovalent or divalent, and the former is incomplete, inhibiting, or blocking antibody. In point of fact, there is no definitive evidence that literally monovalent antibody exists; more precisely, some kinds of antibody behave as if they were monovalent and inhibit or block reaction of antigen with divalent antibody. In the case of monovalent haptenes, valency is predetermined, but this is not true of incomplete antibody. It is possible, for example, that in some instances antibody may in fact be divalent but that the reactive sites are too close together to permit reaction with more than one molecule of antigen at the same time.

The existence of divalent antibody is, on the other hand, firmly established by extensive and precise studies showing that, in antigen excess, each antibody molecule combines with two molecules of antigen. The two antibody valencies are apparently always of the same specificity in a single molecule; *i.e.*, in the immune response to two or more antigens given simultaneously, a single antibody molecule does not have one valence specific for one antigen and the other specific for another.

Complex formation. The initial primary union of antigen and antibody occurs very rapidly and is usually complete within a few minutes, even at low temperatures. The aggregates which appear as a visible precipitate are formed over a longer period, as much as several hours. The aggregate material apparently consists of antibody molecules fairly tightly packed around antigen molecules, with some of the antibody molecules forming bridges between these units to give chains and a loose network of the complex. When either antigen or antibody is monovalent, or behaves as if it were, the available valences are satisfied, bridges, and therefore aggregates, cannot be formed, and there is no precipitate.

Composition of the complex. Whether or not visible aggregates of antigen and antibody occur, their relative content of antigen and antibody is determined by the proportions in which antigen and antibody are mixed. In this respect, three zones are to be distinguished, viz., the zone of antibody excess in which the proportion of antibody to antigen is large, and excess antibody is uncombined and demonstrable in the supernatant; the zone of optimal proportions, or equivalence zone, in which there is no uncombined antigen or antibody; and the zone of antigen excess in which antigen is present uncombined.

With respect to the formation of visible precipitate in the zones of antibody excess and antigen excess, two kinds of systems are differentiable. In one of these, the horse or H type, so-called because it is characteristic of the horse antitoxin-toxin system,

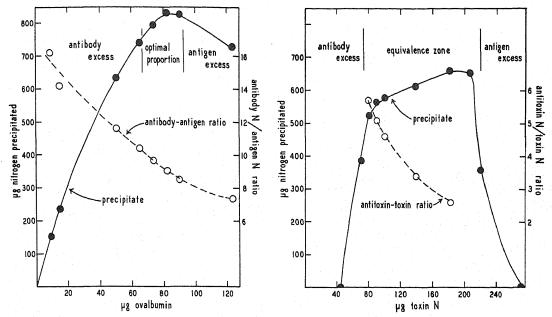

Figure 69. The two types of precipitin systems. Left, the "rabbit" type, in which the complex is not soluble in the zone of antibody excess; precipitate produced by adding varying amounts of ovalbumin to 1 ml. of rabbit anti-ovalbumin serum. (Data of Heidelberger and Kendall.) Right, the "horse" type, in which the complex is soluble in either antibody or antigen excess; total nitrogen precipitated from 1 ml. of diphtheria horse antitoxin by varying amounts of toxin. (Data of Pappenheimer and Robinson.)

precipitation is inhibited in an excess of either reagent. In the other, characteristic of most antigen-antibody systems and called the rabbit or R type because antiserums prepared in the rabbit are usually used, precipitation is not inhibited in the zone of antibody excess, and in this region all of the antigen is precipitated so that the amount of precipitate formed is determined by the amount of antigen added. These two types of precipitating systems are illustrated in the accompanying figure.

The failure to form precipitate, or other manifestation of the antigen-antibody reaction in the zone of antibody excess is called the prozone phenomenon. In the case of the toxin-antitoxin system, this is due to the formation of antigen-antibody complexes which do not aggregate. In practice, however, the prozone phenomenon occurs in all kinds of antigen-antibody reactions and even in in vivo protection tests (Schwellenwert). So it need not be due to the solubility of the complex in excess antibody. For example, there may be simply insufficient antigen present to give a precipitate. Or, when adequate amounts of antigen are present, as in bacterial agglutination, the particulate antigen may be rapidly saturated by antibody, leaving no functional valences available for the formation of antibody bridges; *i.e.*, the particles are soluble complexes. The inhibition of precipitation in antigen excess is theoretically due to the formation of soluble complexes, and this may be regarded simply as a consequence of the presence of antibody in amounts too small to aggregate the antigen present.

The bulk of the precipitate formed with soluble antigen is antibody. Measured by weight, the ratio of antibody to antigen may be quite small when the antigen molecule is very large, but with small antigen molecules it may be as much as 100, a consequence of surface-volume relationship in the antigen molecule. The molecular ratio of antibody to antigen may be determined in closely defined systems; with bovine serum albumin antigen and rabbit antibody, for example, the molecular ratio varies from about 6 in the zone of antibody excess to approximately 3 in the zone of antigen excess.

The optimal proportion or equivalence zone is, as indicated above, the antigenantibody ratio at which neither antigen nor antibody is present in uncombined form. In practice this is readily determined by the

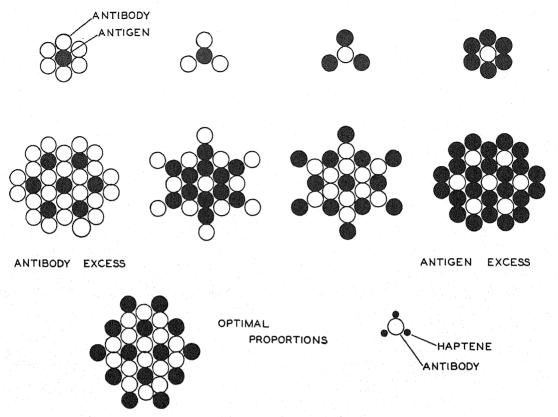

Figure 70. Diagrammatic representation of possible arrangements of antigen and antibody molecules in the complex. (Modified from Marrack.)

precipitin ring test (Chap. Fourteen) applied to the supernatant. This usually, though not invariably, coincides approximately with the antigen-antibody ratio giving a maximum amount of precipitate, and that at which precipitate first appears. The last criterion is the one usually used in toxinantitoxin flocculation. The titration may be carried out by using a constant amount of antibody mixed with varying amounts of antigen or by keeping the antigen constant and varying the antibody concentration. The former, designated the α -type procedure by British workers, is usually used, but the latter, the β -type procedure, is used for toxin-antitoxin titration. The two may give slightly different results, designated as the α -type optimum and the β -type optimum respectively, but usually a different β -type optimum is poorly defined or does not occur.

The ratio of antibody to antigen in the zone of optimal proportions is a constant for any given system; i.e., the ratio is the same when the concentrations are varied, and therefore constitutes one of the most

precise measures of antibody content of an antiserum. It occurs over a narrow range when a single antigenic specificity is concerned, and the antigen molecules are uniform, but takes the form of a plateau when more than one antigenic specificity is concerned, or when the antigen molecules, such as those of pneumococcal polysaccharide, vary in size and number of combining sites.

Mathematical analysis. A number of theories of the interaction of antigen and antibody have been proposed, and the modern theories date from Bordet's postulation of the reaction as an adsorption phenomenon. One of the first of these was that of Heidelberger,²⁹ who assumed that the reaction was similar to a chemical one between substances multivalent with respect to one another and behaved according to mass action to give a series of bimolecular reactions. Using the conventional symbols Ab = antibody and Ag = antigen:

 $Ag + Ab \rightarrow Ag.Ab$ $Ag.Ab + Ag \rightarrow AgAb.AG$ $AgAb + AgAb \rightarrow AgAb.AgAb$ and so on in the region of excess antibody, with the formation of visible aggregates having the general formula $(Ag_nAb_m)_x$. This leads to a general description of the precipitation reaction in the zone of excess antibody:

$$AbN = 2Rx - \frac{R^2}{AgN}x^2$$

where R = AbN/AgN and x = antigen precipitated. Since it is assumed that the reactions are irreversible, this holds only in the zone of antibody excess.

Hershey's^{30, 31} more intensive mathematical treatment is based upon the assumption the antigen-antibody union occurs as a series of reversible reactions which are unaffected by aggregation and may be represented as

On analysis, this approach gives the Langmuir absorption equation

$$R = \frac{ab[Ag]}{1 + b[Ag]}$$

in which R = the ratio of antigen in the precipitate [Ag], to the concentration of antibody in the supernatant, and a and b are constants. Equations of this type fit the linear relation between antigen-antibody ratios in the precipitate to the concentration of antibody in the region of antibody excess, and to the concentration of antigen present in the supernatant in the region of antigen excess.

Using a treatment identical with that of the dissociation of a polybasic acid, and assuming that antibody behaves as if it were monovalent, Teorell⁸⁸ arrived at the relationship

$$[Ab] = Ab - [Ag](p_1 + p_2 + ...)$$

when [Ab] and [Ag] represent the concentrations of free antibody and free antigen respectively in the supernatant, Ab the total amount of antibody present, and p_1 , p_2 . etc., represent the values $[Ab]/k_n$, $[Ab]/k_nk_{n-1}$, etc., in which k_n , k_{n-1} , etc., are the several equilibrium constants. This treatment allows a fairly accurate prediction of the course of the precipitation reaction over its entire range when reasonable as-

sumptions of solubilities and valence are made.

The most comprehensive treatment is that of Goldberg, 25 which is stochastic in taking into account the known heterogeneity of antibody present in immune serum by calculating the most probable distribution of molecular species by the methods used to study the distribution of molecular size of branched chain polymers. It assumes both divalent and monovalent antibody and multivalent antigen which react to produce branched chains until the system reaches a point at which it consists largely of relatively few large aggregates, and precipitation occurs, but no arbitrary parameters are introduced for the purpose of curve fitting. On this basis m_{ijk} , the number of aggregates composed of i divalent antibody molecules, j monovalent antibody molecules, and kmultivalent antigen molecules, is given as

$$\begin{split} m_{ijk} = & fG \; \frac{(fk-k)!}{(fk-2k+2-q-j)!k!q!j!} \; r^{k-l} \; p^{k+l+l} \times \\ p^{k+l+j-1} \; (1-p)^{+fk-k-l-j+1} \; (1-\rho \; pr)^{l-k+1} \; (1-\rho) \end{split}$$

when

$$i = k - 1 + q \text{ and}$$

$$O \le q + j \le fk - 2k + 2$$

and G = the number of molecules of antigen in the system, f = the valence of each antigen molecule, q = the number of free antibody valences in an aggregate, p = the proportion of antibody valences in the system that have reacted, ρ = the proportion of antibody valences on divalent antibody molecules, A = the number of divalent antibody molecules in the system, r = fG/2A, and s = fG/D where D = the number of monovalent antibody molecules.

Provided that the initial composition of the system, the valence of the antigen, and the extent of the reaction are known, this expression allows the calculation of the number of every kind of aggregate in the system, and the point at which very large aggregates are formed, and precipitation occurs.

The critical condition at which the complex takes the form of very large aggregates to give precipitation may be calculated from a simpler formulation derived from the above, viz:

$$\gamma p^2_c = \frac{1}{V-1}$$

when γ = the ratio of antigen valence to antibody valence, p_c = the critical fraction of antigen valences bound, and V = the valence of the antigen. It may be calculated that when the valence of antigen is 2, the formation of large aggregates occurs only in a mixture in which there is an equal number of antigen and antibody valences. With higher antigen valence, the range over which precipitation can occur becomes broad; for example, with an antigen valence of 6, precipitation can occur over a 25-fold range in the ratio of antigen valence to antibody valence, and with an antigen valence of 100, the range is 10,000-fold.

The occurrence of precipitation is also affected by the dissociation constant for, when the concentration of antibody is low relative to its dissociation constant, a significant portion of antigen and anti-body valences are uncombined. For example, with an antigen valence of 6, precipitation cannot occur when the antibody concentration is equal to or less than the dissociation constant. It follows also that the critical conditions for the formation of very large aggregates may occur in lower concentrations of antibody when the valence of antigen is large. This is consistent with the general observation that the larger the antigen, e.g., bacteria and erythrocytes, the less antibody is required and the higher the apparent antibody titer.

As pointed out earlier, the precipitin reaction may be regarded as a logical extension of the initial antigen-antibody union. It is perhaps incidental, as will appear, that toxin is neutralized by antitoxin, but the cytotoxic effects of antibody, or complement mediated by antibody, when the antigen is cellular would appear to be set somewhat apart from considerations such as these.

Chapter Fourteen

IMMUNITY

The Serological Reactions

The variety of consequences of the primary union of antigen and antibody make up the so-called second stage of the antigenantibody reaction. These occur in vitro and, with the exception of certain kinds of protection tests (see below), are test tube reactions. Since the antibody is usually that contained in serum, these reactions are called serological reactions, and the general subject matter, serology. Strains of microorganisms differing in their antigenic structure and separated and identified by serological means are, for example, serological types or serotypes.

The serological reactions are extremely useful for a wide variety of purposes including serological identification of microorganisms and the resolution of their antigenic structure, measurement of the immune response, serodiagnosis of infectious disease by testing patients' serum for the presence of antibody to suspected etiological agents, etc.

The nature of the secondary stage of the antigen-antibody reaction is dependent upon the way the test is carried out, as noted earlier. In general, two kinds of effects are observed, the one an aggregation of soluble or particulate antigen in an overtly apparent way, and the other a cytotoxic action when the antigen is a living cell, that may result in death of the cell, changes in its permeability, or actual dissolution of the cell structure, all of which may be observed in vitro.

On the basis of the way in which the secondary stage occurs, several "kinds" of antibodies are distinguished. These are:

The precipitins or precipitating antibodies which aggregate soluble antigens.

The agglutinins which agglutinate or aggregate particulate antigens, including cells in suspension.

The antitoxins which specifically neutralize the pharmacological action of microbial toxins, especially exotoxins.

The *lysins* or antibodies which mediate dissolution of part or all of the structure of a cellular antigen by complement.

The opsonins which markedly facilitate the ingestion of cellular or other particulate antigens by the phagocytic cells of the body.

The protective or neutralizing antibodies which neutralize the infectivity of pathogenic microorganisms and protect the animal against infection and disease.

In addition to these, an animal may be made hyperreactive or hypersensitive to antigenic substances by a preliminary inoculation, and the consequences of antigen-antibody union are apparent only in living tissue, in vivo, or in vitro in certain kinds of preparations. This will be considered elsewhere (Chap. Fifteen), and the various serological reactions here. The specific technical detail of such reactions may be found in various compilations. ^{9, 27, 44}

PRECIPITINS

The precipitation of soluble antigen in the presence of homologous antibody by the formation of large aggregates of the antigen-antibody complex has been described earlier (Chap. Thirteen). In this kind of serological reaction the antibody functions as a precipitin, and the antigen which provokes its formation is known as a precipitinogen. The physical state of the antigen used for immunization is not of particular importance; antibacterial serums, for example, will give precipitates when mixed with preparations of the soluble cell substance of the microorganisms, and precipitins may almost always be demonstrated in lytic, antitoxic, opsonic and agglutinating antiserums.

Precipitation does not occur in the absence of electrolyte and does not require the presence of heat-labile substances such as complement.

The precipitin test is carried out with undiluted, or only slightly diluted, serum, but the antigen solution is diluted in series. The reagents may be mixed in the usual way, or the antiserum may be pipetted into very small test tubes and the solutions of diluted antigen carefully layered on top with no mixing. In the first instance a precipitate is formed which settles out like agglutinated bacteria, while in the second a precipitate forms at the interface between serum and antigen solution. The latter test is termed a "ring test." The end point of either test may be taken as the highest antigen dilution with which the serum forms an observable precipitate and the titer of the serum given in these terms. Potent antiserums may have extremely high titers, precipitating antigen in dilutions of 1:100,000 to 1:5,000,000.

quantitative precipitin reaction. 13 While such precipitin titers are indicative of the amount of antibody present, a more precise measure is the amount of antibody precipitated from a known amount of antiserum at the equivalence zone. The test is usually carried out by adding increasing amounts of antigen to a constant amount of antiserum. The end point is indicated approximately as that proportion of antigen and antibody which gives the maximum amount of precipitate, and precipitation usually appears first at this point. The equivalence zone, it will be recalled, is that proportion of antigen and antibody such that neither is in excess, i.e., present in the supernatant, and is demonstrated by application of the precipitin ring test to the supernatant. Precipitate formed at the equivalence zone may be removed by centrifugation and analyzed for nitrogen by the usual micromethods to give, by difference, the total antibody nitrogen present. In precise quantitative work the co-precipitation of other nitrogenous sub-

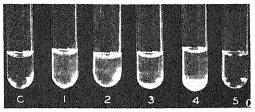

Figure 71. The precipitin reaction. Note the precipitate in tube 4 in maximal amount and the failure of precipitation to occur in the control tube (C) and tube 5, in which the antigen dilution is too great to form a visible antigen-antibody aggregate.

stances must be taken into consideration. The largest contribution of this kind is complement (see below), and for accurate results the antiserum examined must be decomplemented by treatment with some heterologus antigen-antibody system.

Precipitin reactions in gels.4,59,60 When antiserum is incorporated in a gel, such as gelatin or agar, and antibody allowed to diffuse into the gel, or when antigen and antibody diffuse toward one another in a gel, the precipitin reaction occurs as a band of precipitate. This phenomenon is known as immunodiffusion. The band is sharp when the proportion of reactants approximates that of the equivalence zone, but commonly this is not true, and the leading edge is sharp while the trailing edge is more diffuse. Since individual antigens form individual bands of precipitate with their homologous antibodies, the gel diffusion method allows the demonstration of antigenic heterogeneity because a mixture of antigens gives multiple bands of precipitation. The number of components so observed is a minimum, for there is no assurance that other components are not present but in too small amount to produce visible bands, and what appear to be single bands may sometimes be differentiated or resolved into more than one band.

There are a number of variations in the gel diffusion technique. The single diffusion method of Oudin makes use of antiserum-containing agar or gelatin in a small bore tube which is overlaid with a solution of antigen. On standing for some days, the antigen diffuses into the antibody-containing gel with the development of bands of precipitation. In a single antigen-antibody system only one band is formed, while multiple systems give a group of bands corresponding to the number of systems

present in appropriate amounts and proportions.

A double diffusion technique was developed by Ouchterlony in which antigen and antibody are placed in wells in an agar gel and allowed to diffuse toward one another to form a band of precipitate. Elek has used a similar method in which strips of filter paper soaked in antigen solution and in antiserum are placed on the surface of an agar gel. In the double diffusion technique multiple wells may be used; e.g., two antigen solutions may diffuse simultaneously toward the same antiserum. The bands of precipitate forming between each of the antigens and the antiserum fuse at their juncture when the two antigens are the same but cross independently when the two antigens are different.19 At the same time, multiple precipitates may be formed by a single antigen-antibody system, usually when the immunodiffusion is carried out with strongly unbalanced reactant ratios, or when the process is subjected to sudden changes in temperature.

Assay of antigen, or antibody, mixtures by precipitation in gels is based not only on the formation of successive bands of precipitate, but also on the rate at which they diffuse through the gel. The relation between the logarithm of the antigen concentration and square of the migration rate is linear under conditions of free diffusion, and superimposed bands may sometimes be resolved by adjusting the concentrations of the reactants. Oudin, for example, showed that the band of precipitate advances in the single diffusion method according to

$$h = k \sqrt[2]{t}$$

in which h = the distance traversed by the leading edge of the band, t = time, and k is a constant. Since k varies with the concentration of antigen and antibody, it is an index of the concentration of either reactant when the other is known. The viscosity of the gel, the presence of contaminants in the reactants, etc., affect k, and in general the quantitative approach to gel diffusion has not as yet given precise results.

The method has, however, been extremely useful qualitatively. For example, it has been possible to demonstrate by this means the presence of more than one antigenic component in highly purified diphtheria toxin otherwise apparently homogeneous. It also has practical application in this connection in the "in vitro virulence test" for toxigenic diphtheria bacilli; the bacteria are grown as a streak on an agar medium near to a strip of filter paper soaked in antitoxin, and a band of precipitate forms between the two when the bacterial strain is toxigenic.

Immunoelectrophoresis. 20, 31, 32 The technique of immunodiffusion may be combined with electrophoretic separation of one of the reactants, commonly the antigen. This is carried out by preparing the gel, commonly agar, in a thin strip on the surface of glass, applying the antigen in a well in the gel, and separating the components of differing mobility, the gel serving as a supporting medium. The separated material is then reacted with antiserum placed in a trench extending the length of the separation. Bands of precipitate occur about the separated antigenic components which may be stained, photographed, etc. This kind of immunoelectrophoretic analysis is usually carried out on a micro scale, i.e., in thin

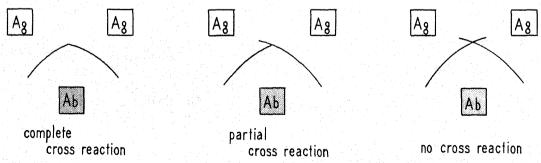

Figure 72. Diagrammatic representation of the Ouchterlony double diffusion technique with single bands of antigen-antibody precipitate. Left, the juncture of the bands indicates identity of the antigens; center, a partial cross-reaction; right, the independent behavior of the bands indicates no relation between the antigens. In all cases the antiserum contains antibody to both antigens.

367

layers of gel on a glass microscope slide. It has very considerable utility in the differentiation of differently charged antigens, as in ultrasonic lysates of bacteria, or the multiplicity of antigenic proteins present in serum.

AGGLUTININS

Precipitin reactions with haptenes. The precipitin reaction occurs not only between antibody and complete antigen but also with some partial antigens or haptenes. An antipneumococcus serum, for example. will react not only with a solution of the pneumococcus cell substance but also with pure capsular polysaccharide. When the haptene is of high molecular weight, as in the case of the polysaccharides, a visible precipitate is formed, but when it is a simple compound such as an organic acid or monosaccharide no observable precipitate appears. The reaction between antibody and such haptenes may, however, be shown by the fact that antiserums treated with haptene will no longer precipitate the complete antigen; the antibody has already reacted with the partial antigen.

Cross-reactions. The precipitin reaction, like the other immunological reactions, is highly specific, but cross-reactions are observed between similar antigens. With naturally occurring antigens, antigenic relationships tend to parallel phylogenetic relationships, as among the serum proteins of related animal species described elsewhere (Chap. Thirteen). Among artificial conjugated antigens, cross-reactions are associated with similarities in the structures of the attached haptenes. In precipitin and other immunological cross-reactions between naturally occurring antigens, it has not been possible to differentiate unequivocally between those occurring as a consequence of similar determinant structures and those that occur because of the presence of the same antigenic specificity in two otherwise differentiable antigenic mosaics.

In any case, the specificity of the precipitin reaction is such that it differentiates sharply between unrelated soluble antigens and is the serological reaction usually used for the identification of blood stains, etc., for forensic purposes.

AGGLUTININS

If the blood or serum of an animal previously immunized against a bacterium is mixed with a suspension of the microorganisms, the latter become immobilized and in a short time aggregate to form large clumps of cells. In the slide agglutination test, commonly used for rapid identification purposes, the antigen is used as a milky suspension and the antiserum undiluted or only slightly diluted: the suspended bacteria aggregate in the presence of homologous antibody within a minute or two to give a curdled appearance to the suspension. In the test tube these clumps settle out, and the turbid bacterial suspension is cleared with the formation of a precipitate-like mass of clumped cells in the bottom of the tube. This phenomenon is termed agglutination. and the bacterial cells are said to be agglutinated. The bacteria are not killed by agglutination and will, in fact, grow in immune serum although with altered morphology and the formation of long chains of bacillary forms. Living bacteria need not be used for the agglutination reaction, for dead bacteria are agglutinated as readily as the viable forms.

Although many species of bacteria may be clumped by "normal" serums in low (1:5 to 1:10) dilutions, the capacity of a serum to agglutinate bacteria is greatly enhanced by immunization; high-titered antiserums may be prepared which will bring about agglutination in dilutions of 1:20,000 to 1:50,000. The agglutination reaction is, then, an antigen-antibody reaction, and the antibody is designated an agglutinin. The antigen is sometimes termed an agglutinogen. The agglutinin does not require the cooperation of complement or other heat-labile substances, and inactivated serums will agglutinate to titer.

Not only bacteria but a variety of free cells, including erythrocytes and others, are agglutinated by normal and immune serums. The incompatibility of human blood groups is a consequence of the presence of hemagglutinins. Hemagglutinins are also formed by some bacteria and may possibly be instrumental in the formation of the thrombi observed in the blood vessels after death from certain of the infectious diseases.

Agglutination is highly specific, an antiserum agglutinating only the homologous antigen, and agglutination does not require complement. The reaction may be observed microscopically by mixing a suspension of bacteria and diluted antiserum on a slide but is most commonly carried out by mixing

the two in 0.5 to 1.0 ml. amounts in small test tubes and observing the formation of a precipitate. In the latter instance, varying dilutions of serum (frequently prepared in geometrical progression by mixing with an equal amount of physiological salt solution, i.e., 1:10, 1:20, 1:40, 1:80, etc.) are added to the bacterial suspension and incubated at 37° C. overnight or at 55° C. for two hours. The highest dilution showing observable flocculation is taken as the titer of the serum: a serum showing agglutination in a dilution of 1:10,000 but not in 1:20,000 is said to have an agglutinin titer of 1:10,000. Such titers are variable to some degree, depending upon the density of the bacterial suspension and other factors; light suspensions, for example, showing only a faint turbidity to the eye may give somewhat higher agglutinin titers than heavy suspensions.

Conglutination and conglutinating complement adsorption. 14, 38 It was observed by Bordet and Gay in 1906 that fresh serum of some animals will agglutinate erythrocytes treated with cow serum. The cow serum is the source of two factors: natural antibody for the erythrocytes, and the clumping activity, conglutinin. The reaction was termed conglutination to distinguish it from agglutination, which does not require complement. This reaction may be used as an indicator system in the same manner as the sheep-hemolysin system of the complement-fixation reaction, the presence or absence of free complement being indicated by conglutination or conglutination inhibition. Used in this way, it is called a conglutinating complement adsorption test (CCAT). It has become of renewed interest in connection with the serodiagnosis of Q fever and organisms of the psittacosislymphogranuloma group.

Passive agglutination.⁵⁶ Particles upon which soluble antigen is adsorbed acquire in a passive sense the antigenicity of that antigen and behave as if they were composed of that antigen. They agglutinate in antiserum to the soluble antigen, and the agglutination is said to be passive agglutination. This phenomenon illustrates the essential identity of precipitin and agglutinin, i.e., in the precipitin reaction molecules are aggregated or agglutinated, while in the agglutination reaction particulate material is agglutinated.

Antigen may be adsorbed on collodion, latex or similar particles of appropriate size, but red blood cells, usually of the sheep, have been the most commonly used for this purpose, and the reaction is a passive hemagglutination. Soluble antigens are usually adsorbed relatively rapidly, polysaccharides in 10 to 30 minutes, and proteins a little more slowly. The adsorption of protein may be facilitated by a preliminary treatment of the red cells with dilute (1:20,000) tannic acid. Stable preparations of formalinized, tannic acid-treated red cells may be used instead of fresh cells.21 A variety of antigens have been used, including polysaccharide haptenes, soluble antigens from microorganisms such as tuberculin, the O and Vi antigens of enteric bacilli, etc., bacterial toxins such as tetanus toxin, and certain viruses such as adenoviruses.

The original antigenicity of the red cell is not lost when a soluble antigen is adsorbed on its surface. This is a significant factor when sheep erythrocytes and rabbit antiserums are used, for these cells contain Forssman antigen, and antibody to this antigen is commonly found in serums of animals, such as rabbits, which do not contain the antigen. Consequently, sheep cells are often agglutinated in rabbit serum, and if these reagents are used, the antiserum must be treated with normal sheep cells to remove the Forssman antibody by absorption (see below) before use. Or this artifact may be avoided by using rabbit erythrocytes.

The passive hemagglutination test is often more sensitive than bacterial agglutination owing to the relatively large size of the antigen particle. Antibacterial serums having homologous antibacterial agglutinin titers of 1:5000 to 1:10,000 may agglutinate red cells sensitized with soluble bacterial antigen to titers of 1:50,000 or more.

The antiglobulin reaction. 15, 22 The antiglobulin reaction is a passive agglutination in which the antigenic cell or particle is treated, first with antiserum specific for its surface antigen, and then with antiserum to the serum globulin of the specific antibody. It is also known as the Coombs test. In the first stage of the reaction, an ordinary agglutination or passive agglutination, homologous antibody in the form of immune globulin reacts specifically with its antigen. When the immune globulin is thus specifically

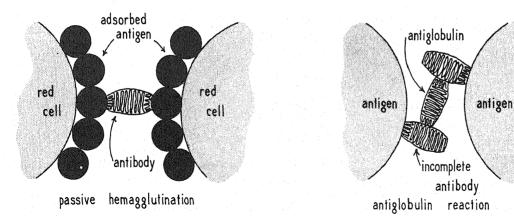

Figure 73. Diagrammatic representation of the passive hemagglutination reaction (*left*) and the antiglobulin reaction (*right*). Note that the antigen-antibody reaction is between antibody and adsorbed antigen in the first instance and between incomplete antibody globulin molecules and their homologous antibody in the second.

adsorbed onto the particle, the particle behaves antigenically as if it were serum globulin. On the addition of antibody to the globulin, antiglobulin, the immune globulin that acted as an antibody in the first instance now acts as an antigen, and the coated particles are agglutinated. While, then, in a technical sense the second reaction is specific, the specificity of the antiglobulin reaction as a serological reaction lies in the specificity of the original antigen and its antibody.

This reaction is particularly useful for the titration of incomplete antibody which will of itself not agglutinate a particulate antigen. It does, however, react with antigen to adsorb onto a particulate antigen, which then becomes susceptible to agglutination with antiglobulin serum. In other words, the incomplete antibody behaves as if it were monovalent, but as an antigen it is multivalent. For example, a bacterial antigen is agglutinated in its homologous antiserum by the complete antibody present. If, however, antibody to the immune globulin is added to the system, the bacterial cells which reacted with incomplete antibody will now agglutinate. Antiglobulin titers are frequently higher than agglutination titers, because the latter titrates only complete antibody, while the former titrates both complete and incomplete antibody. In some instances, notably that of Rh antibody, antibody is largely incomplete and agglutination occurs, for all practical purposes, in the antiglobulin reaction.

Cross-reactions. Although the agglu-

tination reaction is highly specific, certain cross-reactions between closely related bacterial species are frequently observed. Such reactions are attributable not to a lack of immunological specificity but to the immunological heterogeneity of the bacterial cell. As indicated earlier (Chap. Thirteen). the cell is made up of a variety of antigenic components, an "antigenic mosaic." Clearly, then, if the same component is present in each of two species of bacteria, an antiserum prepared against the one will agglutinate the other but generally to a reduced titer, i.e., only in the lower serum dilutions. This sharing of antigenic components and the resulting cross-reactions are particularly common among the gram-negative enteric bacilli. The agglutining responsible for such cross-reactions are sometimes referred to as "group agglutinins" and the phenomenon as "group agglutination."

Agglutinin adsorption. The direct demonstration of the antigenic heterogeneity of a bacterium and the consequent multiple antibody content of its homologous antiserum are made possible by agglutinin adsorption. If a heavy suspension of bacteria is prepared in diluted (commonly 1:5) antiserum, incubated for two to three hours and centrifugated, the supernatant diluted serum will be found to have lost its ability to agglutinate the bacterium with which it was absorbed; the agglutinins for that microorganism have been taken up by the bacterial cells, leaving other agglutinins intact. In practice it is necessary to absorb two or three times and, since the phenomenon is

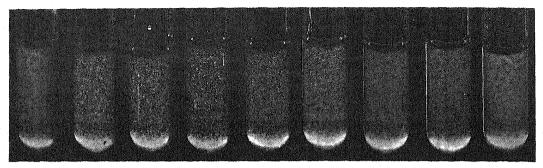

Figure 74. The macroscopic agglutination test—flagellar agglutination of Salmonella. The control tube (at left) contains bacterial suspension but no antiserum. Successive dilutions in the remaining tubes from left to right are 1:100, 1:200, 1:500, 1:1000, 1:2000, 1:5000, 1:10,000, and 1:20,000. Note agglutination in 1:10,000 but not in 1:20,000.

an adsorption, it is not always possible to remove completely the agglutinins in question.

This preferential adsorption makes possible the breakdown of the antigenic mosaic of the bacterial cell into component parts. For example, an antiserum prepared against a bacterium containing antigens A, B, and C will contain antibodies a, b, and c. If such an antiserum is absorbed by a second bacterium which contains antigens B and C, antibodies b and c will be removed leaving a intact, and the antiserum will still agglutinate its homologous bacterium. Suppose an antiserum is prepared against the second bacterium which will contain antibodies b and c. If this serum is absorbed by the bacterium containing antigens A, B, and C, it will no longer agglutinate its homologous antigen, for all the antibodies will have been removed. Clearly, then, the complete absorption of a known serum by an unknown organism does not indicate that the unknown organism is necessarily immunologically identical with that with which the known serum was prepared; to prove such immunological identity a "mirror absorption" must be carried out, i.e., each antiserum absorbed with each organism.

The agglutination test and agglutinin absorption, although used to some extent in the diagnosis of infectious disease, have been found particularly valuable in the study of the relation of bacterial species to one another and in some instances, as in the case of Salmonella (Chap. Nineteen), complex antigenic formulas have been worked out. The determination of the components of the antigenic mosaic of a bacterial species is termed antigenic analysis.

H and O agglutination. A number of bacterial species, particularly Salmonella, Proteus, and certain others, may agglutinate in two ways.

Macroscopically the H agglutination gives rise to a loose, flocculent precipitate, and upon microscopic examination it may be observed that the bacterial clumps are loose, the flagella of the microorganisms being entangled with one another. The O agglutination, on the other hand, produces a finely granular precipitate in which the individual bacterial cells are closely packed together. These types of agglutination are a consequence of the presence or absence of the flagellar, heat-labile H antigen. Immunization with the whole bacterial cell containing both flagellar and somatic antigenic components gives rise to antiserums containing both types of antibody, the H generally in high titer while the O antibody is commonly active in dilutions of less than 1:1000.

Spontaneous agglutination. Some strains of bacteria do not form stable suspensions and are said to be spontaneously agglutinable. This behavior is particularly characteristic of rough variants and, although not an immunological phenomenon, is frequently of practical importance in agglutination studies.

Cold agglutinins. In some diseases socalled cold agglutinins, which agglutinate human O group erythrocytes at O° C. but not at 37° C., are present in the serum. They are found in one-half or less of cases of primary atypical pneumonia and have limited utility in eliminating certain other infections, such as Q fever, in the diagnosis of this disease. The titer reaches a peak early in convalesence, but the agglutinin has, so far as is known, no immunological status, for it is found in other diseases such as trypanosomiasis and hemolytic anemias, and it may appear following sulfonamide therapy.

The mechanism of agglutination. The clumping of bacteria under the influence of immune serum may be taken as evidence per se that a force attracting the cells to one another is operative, at least at times. Similarly, the fact that bacteria are not in a constant state of agglutination is indicative of a force which tends to hold the cells apart from one another. The attractive or cohesive force is probably that of surface tension, i.e., the interfacial tension at the cell surface, and the repulsion that of like electrical charges, for, as pointed out previously, bacteria are negatively charged at pH's compatible with viability. On the basis of such reasoning it would appear that the balance between these opposing forces determines whether the microorganisms will form a stable suspension or whether they will clump together and settle out.

It was early observed that the presence of an electrolyte is essential to agglutination: if both immune serum and bacterial suspension are dialyzed free of salt before mixing, the cells are not agglutinated, but if a tract of salt is added to the mixture, agglutination takes place at once. This behavior, it will be seen, corresponds to that of a mixture of two colloids of opposite charge, such as gum mastic and gelatin, when the one is added in too small an amount to precipitate in the absence of salt. That the repelling effect of electrical charge is an important factor is also indicated by the agglutination of bacteria in the absence of antibody when the pH is lowered to the iso-electric point of the cells, a phenomenon termed acid agglutination. It was formerly thought that bacterial species might be sharply differentiated from one another on the basis of the pH of their acid agglutination, but this has not proved to be true.

The agglutination of bacterial cells is, however, a function not only of electrical charge on the cells but also of the cohesive forces tending to draw them together. Studies in which both potential difference (between the cells and the suspending medium) and cohesive force were directly measured have shed considerable light on the mecha-

nism of agglutination. It has been found that electrolytes in low concentration (0.01 N) affect primarily the potential, and in high concentration also decrease the cohesive force. If the cohesive force is not affected, agglutination occurs when the potential is reduced below the critical point of 15 mv. If, however, the cohesive force is decreased, the critical potential is also decreased, and, therefore, in concentrated salt solutions agglutination does not take place even though there is no measurable potential. Immune serum, presumably adsorbed on the surface of the bacterial cells, while reducing the charge somewhat appears to function by preventing the salt from decreasing the cohesive force, and agglutination occurs at the critical point of 15 mv. Furthermore, if the potential difference is reduced by electrolyte to 15 mv. or less in a bacterial suspension, the addition of immune serum raises the reduced cohesive force, and agglutination takes place. Examination of typhoid bacilli by the electron microscope in the presence of immune serum has shown that the flagella become thickened by the deposition of an antibody film approximately 21 Å thick, and the cell walls become more opaque and less definite in outline. The serum-sensitized surfaces appear to be sticky, not only for one another, but also for other particulate matter.

Serological adhesion. 45, 55 This stickiness may be in part at least the basis of the phenomenon of serological adhesion in which nonspecific particulate material tends to adhere to particulate antigen in the presence of antibody and complement. It was first observed in vivo as an adhesion of platelets to cholera vibrios, trypanosomes, and several kinds of spirochetes to provide the basis for serodiagnostic tests. It is variously known as the Levaditi phenomenon, the Laveran-Mesnil reaction, the Rieckenberg reaction, and as the Brussin or Beladung reaction in the Russian literature. What is probably the same phenomenon was later called immune adherence in a reaction in which bacteria, especially syphilis spirochetes, adhere to red blood cells in the presence of antibody and complement.

The nature of this reaction is obscure. It may be observed *in vitro* as well as *in vivo*; various kinds of particles will function in the reaction, but there are discrepancies as among red cells of varied origin, and

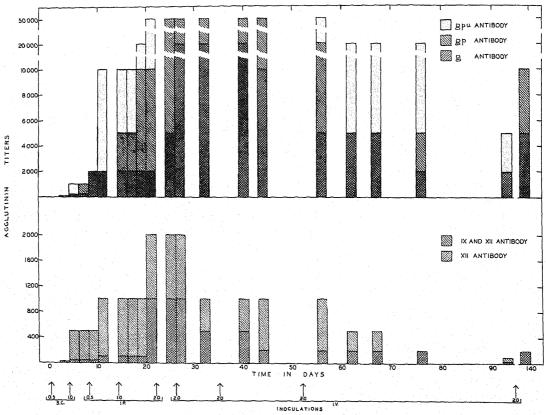

Figure 75. The differential immune response to the components of an antigenic complex as illustrated by the serum antibody response of the rabbit to immunization with Sal. enteritidis var. rostock (Sal. rostock). Agglutinin titers measured against heterologous antigens without antibody absorption. Top, antibody to flagellar antigens; bottom, antibody to somatic antigens.

adhesion has been found to occur with some bacterial antigens but not with others such as Salmonella. This reaction, using human erythrocytes as the adhering particles, has been developed by Nelson as a diagnostic test for syphilis, the *Treponema pallidum* immune adherence, or TPIA, reaction in which the spirochetes are mixed with complement, antiserum, and red cells, and the adherence of the red cells to the spirochetes is observed microscopically *in vitro*.

Blocking antigens. The presence of antigenic cell components may interfere with or prevent agglutination of bacteria by homologous antiserum. The presence of Vi antigen in typhoid bacilli, for example, renders them inagglutinable with homologous O antiserum, but they become agglutinable as the interfering antigen disappears during successive subcultures. Similarly, colon bacilli contain a thermolabile component of the envelope antigen,

the L antigen, which inhibits agglutination with O antiserum, but the bacterial suspension becomes agglutinable when this component is destroyed by boiling. This blocking effect of some antigens may be due to a spatial effect, such as steric hindrance, in preventing the primary union of antigen and antibody; or the inhibition may be one of the aggregation of sensitized cells to give agglutination in the secondary stage of the antigen-antibody reaction.

IMMUNOFLUORESCENT STAINING^{6, 8, 16, 17, 51, 54}

The labeling of immune globulin by conjugation with fluorochromes was originated by Coons in 1942. It had been established that aromatic isocyanates may be coupled with protein by a carbamide linkage with

free amino groups of the protein, commonly the ϵ -amino groups of lysine residues. This reaction is used to couple fluorochromes, most commonly fluorescein or rhodamine as their isocyanates, with immune globulin. The globulin is separated from the other serum proteins by the conventional salting out or methanol precipitation methods and reacted with the fluorochrome isocyanate, and the excess fluorochrome removed by dialysis. The antibody conjugate retains its antibody activity though some changes in other properties may occur.

Homologous antigen is specifically stained through the antibody activity of the conjugate, and may be in particulate form such as bacteria or vegetative virus, or as concentrations of soluble antigen. The application may be direct or indirect: i.e., the antigen may be stained directly with homologous antibody, or indirectly by first treating the antigen with conventional homologous antibody and then staining by the application of fluorescent antibody to the antibody globulin as a variation on the antiglobulin technique described above. In any case, the specifically stained antigen fluoresces in ultraviolet light, requiring appropriate microscopic equipment for observation. Antigen stained with fluores-

The demonstration of dysentery bacilli in the epithelial cells of the midportion of a villus and in the lamina propria of the guinea pig small bowel by fluorescent-antibody staining of a frozen section. The bacilli, coated with fluorescein-labeled antibody, fluoresce a brilliant pale green under ultraviolet light and appear here as white. (LaBrec.)

cein conjugates fluoresces a yellowish green color, and that stained with rhodamine conjugates a reddish orange; both tend to fade on prolonged observation. There are a number of detailed descriptions of the foregoing techniques.^{10, 18, 70}

While much less sensitive than the labeling of antigen or antibody with a radioactive isotope such as I¹³¹, the fluorescent antibody method is much more flexible and has been invaluable in the localization of antigenic substances in the tissues, especially viruses which are otherwise not directly demonstrable. It also has considerable value in the rapid identification of bacteria. 11, 70 Nonspecific fluorescence often occurs but usually may be reduced to insignificance by preliminary absorption of the antibody as, for example, with a brei of the tissue to be stained for contained homologous antigen.

ANTITOXINS

It was found by von Behring and Kitasato in 1890 that the immunity of rabbits and mice that had been immunized against tetanus was associated with the ability of the blood serum to neutralize the toxic substances produced by the tetanus bacillus. The substance in the serum which neutralized the tetanus toxin was designated by these workers as antitoxin. Subsequent investigation has shown that the animal body forms antitoxins in response to the injection of a variety of antigenic poisons, not only those of bacterial origin such as diphtheria toxin, botulinus toxin, and the like, but also against the phytotoxins and zootoxins.

The action of antitoxin may be directly demonstrated in the following way: if a fatal, or many times fatal, dose of toxin be mixed with an appropriate amount of antitoxic serum in vitro, the injection of the mixture into a susceptible animal is wholly without injurious effect; the poisonous qualities of the toxin are nullified by the immune serum. The reaction is, like all other immunological reactions, highly specific, and an antitoxin which neutralizes the homologous toxin is without effect on heterologous toxins.

The toxin-antitoxin reaction. The combination of toxin and antitoxin does not

necessitate the complete destruction of either component; neutral mixtures of toxin and antitoxin may be dissociated by treatment with hydrochloric acid, by freezing in the presence of phenol or tricresol, and, to some extent, by simple dilution. In certain cases, e.g., pyocyaneus toxin and certain snake venoms, in which the toxin is more resistant to heat than the antitoxin, the latter may be selectively destroyed, and the neutral mixture becomes toxic upon judicious heating. It appears, therefore, that a more or less loose combination of toxin and antitoxin takes place, the poisonous properties of the toxin being neutralized as long as the union persists. The rate of reaction between toxin and antitoxin, like the chemical reactions, is dependent upon temperature, concentration, character of the medium in which the reaction occurs, and similar factors. The avidity of an antitoxin for its corresponding toxin differs in different cases; the union between tetanus toxin and antitoxin, for example, takes place less rapidly than that between diphtheria toxin and antitoxin.

An understanding of the precise character of the toxin-antitoxin reaction is dependent upon the interpretation of phenomena revealed by quantitative studies. It might be expected that a given quantity of antitoxin would always neutralize a constant amount of toxin, that the neutralization would follow the law of multiple proportions. This is, however, not the case, and it appears that the amount of antitoxin required to neutralize a given quantity of toxin is dependent upon (a) the manner in which the two are mixed with one another and (b) the relation between toxicity and combining power in the particular filtrate under consideration.

In the first instance it has been observed that when an excess of toxin is added to its specific antitoxin in several portions at proper intervals of time, much more unneutralized toxin remains in the mixture than if the same quantity of toxin had been added to the same quantity of antitoxin at one time. This is known as the Danysz phenomenon. If, on the other hand, antitoxin is added to toxin in successive equal portions, it may be shown that, in general, the first portion of antitoxin neutralizes a greater portion of the toxin than the second, the second a greater than the third, etc.

In the second case it has been found that there is no constant relationship between toxicity and combining power of a toxic filtrate; toxicity slowly diminishes upon storage but combining power remains unchanged. As described elsewhere (Chap. Nine), the toxin is unstable and is slowly converted to toxoid. Both toxoid formed in this way, and that prepared by toxin inactivation with formaldehyde, retain their antigenicity and combine with antitoxin as well as stimulate the formation of antibody when used as immunizing agents. Since the proportions of toxin and toxoid are not fixed, there is only an approximate correspondence between combining power and toxicity, and the toxicity neutralized by a unit quantity of antitoxin may vary from one filtrate to another or in the same filtrate at different times from 30 to 130.

The standardization of antitoxins. quantitative evaluation of the toxin-neutralizing capacity of antitoxic serums is clearly a matter of considerable practical as well as theoretical importance. Ehrlich originally proposed as the standard unit of diphtheria antitoxin that amount which would just neutralize 100 guinea pig MLD's of toxin. As indicated above, however, variability in the relation of toxicity to combining power invalidates any standard based on toxicity; in other words, the combining power of a toxin is not a measure of its toxic qualities. On the other hand, since the combining power of a toxic filtrate remains constant within narrow limits, it is possible to establish an arbitrary standard unit upon which the relative strength of all antitoxic serums can be based. Such a standard diphtheria antitoxin was first prepared by Ehrlich and was preserved by him with all precautions against possible deterioration. A standard antitoxic serum based on Ehrlich's arbitrary standard unit is also prepared in this country by the National Institutes of Health of the United States Public Health Service, and is distributed every two months to the licensed producers of commercial serum. The unit is international, standard serums being tested from time to time under the auspices of the Expert Committee on Biological Standardization of the World Health Organization.52

Titration of neutralizing capacity. Three methods are used in the titration of diph-

theria toxin and antitoxin. The first of these is the classic method of Ehrlich in which two limits (Lat., limes) are determined by guinea pig inoculation. These are the L₀ dose of toxin, which is defined as that amount exactly neutralized by the standard unit of antitoxin, and the L+ dose, that amount of toxin which, when mixed with 1 unit of standard antitoxin, is just sufficient to kill in four days a guinea pig approximately 250 gm. in weight. With these limits established, the serum to be standardized is mixed with the toxin just titrated, and the largest amount of serum which, when mixed with the L+ dose of toxin, will produce a 100 per cent mortality in the inoculated guinea pigs is considered to contain 1 unit of diphtheria antitoxin. This method is not mathematically sound as indicated elsewhere (Chap. Nine), but the dose-response curve to the bacterial exotoxins is so steep that the procedure is practical and so persists.

A second method is based upon the observation that the intradermal injection of 1/250 to 1/500 MLD of diphtheria toxin into a guinea pig is followed by a local reaction, swelling and erythema and, with slightly larger amounts of toxin, necrosis, a phenomenon sometimes called the Römer reaction. By the use of such intradermal inoculations an Lr dose of toxin may be determined, i.e., that amount of toxin, which when mixed with 1 standard unit of antitoxin, will produce the minimal skin reaction. The serum to be standardized is mixed in varying amounts with Lr doses of toxin, and that amount of serum which gives the minimal skin reaction is considered to contain 1 unit of antitoxin. This method has the advantage of allowing the testing of a number of toxin-antitoxin mixtures in one animal but has not displaced the classic method in common usage.

Flocculation. The third method is that of toxin-antitoxin flocculation, sometimes called the Ramon flocculation, and is a precipitin reaction in which the end point is the equivalence zone. Standard antitoxin is mixed with varying quantities of toxin and the tube first, i.e., in time, showing precipitation contains one Lf dose of toxin. Varying amounts of the serum to be standardized are mixed with the Lf dose of toxin. The amount of serum in the tube first showing flocculation in this second series is con-

sidered to contain 1 unit of antitoxin. The precipitation, or flocculation, curve is, as described elsewhere (Chap. Thirteen), of the horse type in which the antigen-antibody complex is soluble in an excess of either reactant, and the Lf dose so determined is the optimal proportion zone of the reaction. This method differs from the other two in that it depends upon the combining power of a toxic filtrate rather than on toxicity. It is generally used, not as a final method of standardization, but as a preliminary to standardization by the Ehrlich method.

The interrelationships of these limits are of some interest. The L+ dose is, of course, larger than the L₀ dose and, because of the peculiarities of the toxin-antitoxin reaction, by considerably more than one MLD. The Lr dose approximates the L_0 dose, as might be expected in view of the small amount of toxin required to elicit the skin reaction. The Lf dose is generally somewhat less than any of these, since it is a measure of combining power rather than toxicity and is unaffected by differences in the proportions of toxin and toxoid. It would appear that the Lf/Lr ratio should be the same for a given toxic filtrate immediately upon standardization. It has been found, however, that this ratio differs with different antitoxic serums because of variation in the avidity of antibody.

Antibody to enzymes. 12, 68 The foregoing discussion of the toxin-antitoxin reaction applies only to the bacterial exotoxins, and diphtheria toxin in particular; e.g., tetanus toxin does not flocculate as rapidly or sharply as does diphtheria or botulinum toxin. Other toxic activities of microbial origin, such as endotoxins, are only incompletely neutralized by antibody, and still others are enzymatic in nature or closely associated with enzymatic activity. The early hypothesis that bacterial toxins might be enzymes has not been borne out in the case of the exotoxins but, in a sense, seems to receive support from theories of the nature of the action of exotoxins such as diphtheria toxin (Chap. Nine) and the enzymatic toxicities.

The way in which antitoxin serves to neutralize the activity of exotoxins in the toxin-antitoxin complex is not known. Some light may be shed on this point, and the partial neutralization of other toxicities, by indirection through the study of the inhibition of enzyme activity by antibody to the

enzyme, for the enzymatic activity represents an activity of the molecule which may or may not be related to its antigenic character.

The degree of inhibition of enzymatic activity in the presence of specific antibody is a function of amount of antibody present. The rate of inactivation, usually titrated by adding increasing amounts of antibody to a constant amount of enzyme, is at first linear, but the rate falls off, and in antibody excess a residual level of activity persists. The amount of residual activity is often related to the size of the substrate molecule, inhibition being substantially complete in the case of proteinases, collagenase, hyaluronidase, etc., and almost complete lack of inhibition is observed only rarely and when the enzyme has a low molecular weight substrate, viz., \(\beta\)-galactosidase, tyrosinase, catalase, etc.

The inactivation may be only apparent in that aggregation of the enzyme in the antigen-antibody precipitate reduces its surface available to the substrate; such apparent inactivation is observed, for instance, with catalase. True inactivation appears to be a matter of steric hindrance, small substrate molecules penetrating between molecules of adsorbed antibody to the active sites on the surface of the enzyme, while large substrate molecules do not. This inference is not only supported by the general, though not invariable, relation of inhibition to size of the substrate molecule, but also by the varied consequences of the order and amount in which antibody and substrate are added to the enzyme-i.e., antibody will not displace substrate—and by kinetic studies which indicate that antibody and substrate do not compete for the same re-

It appears, then, that the site of enzymatic activity and that of antigenic specificity on the enzyme are not necessarily identical. In support of such an inference, cross-reactions between functionally similar enzymes from widely different sources seldom occur, but they do occur between enzymes of closely related origin, and the latter is apparently attributable to antigenic relationships between the proteins rather than the prosthetic groups of the enzymes. While it seems clear that antigenicity and enzymatic activity need not be identical for inhibition of activity

A Property of the Arts New Collections

by antibody, it has not yet been possible to show unequivocally that the two are invariably not identical.

The analogy to the neutralization of toxin by antitoxin will be apparent at this point. The occurrence, or preparation, of toxoids from exotoxins, lacking toxicity but having unimpaired antigenicity, may be taken to suggest that the toxic portion of the molecule may be independent of its antigenic specificity. Similarly, the endotoxins are often said to be poor antigens, since toxicity persists in the presence of excess antibody. They are, in fact, excellent antigens as assaved by the titer of, for example, precipitating antibodies they produce, but the antigen-antibody precipitate at the equivalence zone is toxic although no toxicity is detectable in the supernatant. In a sense, then, the neutralization of toxin by antibody may be only incidental to the antigen-antibody reaction.

LYSINS

It was observed by Nuttall in 1888 that freshly drawn and defibrinated blood, or serum, is markedly bactericidal for many kinds of bacteria and that this property is heat-labile and destroyed by holding at 55 to 56° C. for 30 minutes. Such heated blood or serum is said to be inactivated. This bactericidal effect is a consequence of the presence of natural antibody (Chap. Fifteen) and possibly also properdin (Chap. Nine) in the blood or serum, acting in conjunction with the thermolabile activity known as complement. The antibody concerned is cytotoxic or cytolytic and, because the lytic effect is the one most commonly made use of experimentally, such antibodies are lysins. In functioning as a lysin, the antibody mediates the effect of complement to give a secondary stage of the antigenantibody reaction that is clearly set apart from the primary union or extensions of it.

Pfeiffer phenomenon. One of the first demonstrations of the phenomenon of immune lysis was that by Pfeiffer in 1894 of the lysis of the cholera vibrio in the intraperitoneal cavity of the immune guinea pig. A heavy suspension of the vibrios is injected and samples of peritoneal fluid withdrawn from time to time and examined microscopi-

cally. The vibrios first lose their motility, swell up, and crumble into small fragments, and dissolution of even the fragments follows so that no trace of the bacterial cell remains visible. This phenomenon may also be observed *in vitro* when the vibrios are mixed with antibody and complement.

Cholera vibrios and related microorganisms are relatively fragile, more so than most kinds of bacteria. Immune bacteriolysis may be observed with these microorganisms, and with certain others; for instance, some portion of, but not all, typhoid bacilli so treated will lyse. While lysozyme contained in serum, including complement. and in other body fluids is considered to play a part in the immune bactericidal and bacteriolytic reactions, a residual effect remains after the removal of lysozyme from the system.29 In the case of the cholera vibrio, it has been shown that the cell wall is depolymerized in the presence of the antibody-complement complex in the absence of lysozyme to produce protoplasts which are viable but die because of their osmotic fragility: i.e., the bacteriocidal effect could be completely prevented by the addition of protective substances.25 The bactericidal effect, however, may occur without visible lysis, perhaps by alteration of permeability and loss of cell constituents, and it may be shown by appropriate serological methods that the cellular antigen has combined with both antibody and complement.⁵³

Hemolysis. The lysis of bacteria by an immune serum is not a unique reaction in which only bacterial cells may play a part; bacteriolysis is, rather, a special case of a general phenomenon, for immunization with a variety of cells results in the production of cytolytic serums. Of these, erythrocytes have been by far the most widely studied, for the lysis of these cells, hemolysis, is readily apparent in the test tube; the red opacity of the cell suspension changes to the clear red solution of hemoglobin as lysis proceeds. The stroma is not dissolved but, upon examination, appears misshapen. First demonstrated by Bordet in 1898, hemolysis has been particularly useful not only as a type of lytic reaction peculiarly suitable for laboratory manipulation, but also as an indicator of antigenantibody combination when visible lysis does not or cannot take place. Such immune hemolysins, *i.e.*, those formed by the animal body in response to the injection of erythrocytes, are quite unrelated to the hemotoxins or hemolysins formed by microorganisms.

Complement.^{30, 48, 58, 66} The heat-labile activity participating in the lytic reaction is a constituent of normal serum, and its presence is unrelated to the immune response; *i.e.*, it does not increase in amount during immunization. This activity was called alexin by Bordet, in a restriction of the term as originally applied by Buchner to the undifferentiated heat-labile bactericidal action of blood, and complement by Ehrlich; the latter term is by far the more widely used.

Its status as a normal serum component is clearly indicated by the fact that lytic or bactericidal activity of freshly drawn serum, which has been destroyed by heat inactivation, is promptly restored by the addition of fresh normal unheated serum. There is little species specificity in complement; that from guinea pig serum, for example, may participate in the lysis of beef erythrocytes in the presence of antiserum prepared in the chicken. Some quantitative differences are apparent, for a serum which may be actively complementary in some reactions may be relatively inactive in other combinations, and the total activity is a function of the relative amounts of the various components of complement (see below) that may be present in a given serum.

Properties of complement. The property of inactivation by heat has been referred to above. Complement is also inactivated by shaking, but in neither case is the inactivation completely irreversible, for some activity may be regained on standing. In this respect complement behaves as a typical hydrophilic colloid which can be made to aggregate by physical forces but shows a tendency to spontaneous dispersion and restoration to the original state. The activity disappears upon standing-rapidly at room temperature (two or three hours) and more slowly in the icebox, where it may be preserved for three or four days. It is quite stable at very low temperatures in frozen form, and most of the activity persists after lyophilizing, and in lyophilized form it may be stored in a refrigerator for some months. Complement is irreversibly destroyed by strong acids or alkalis and reversibly inactivated by ions such as Mg. Ca. Ba. Sr. and SO₄ or by hypertonic salt solutions. In this connection it is of some interest that complement which is inactivated by raising the salt concentration to 5 to 10 per cent may be preserved at low temperatures in this form for several weeks, the activity being regained upon dilution with distilled water. These properties and some others, such as ready adsorption on surfaces, suggest a close relationship between complement and the enzymes; it has also been pointed out that there are remarkable resemblances to certain compounds of protein with soaps and lipids. An association of complement with the blood-clotting mechanism is suggested by the observation that many substances have both anticoagulant and anticomplementary activity, and that there is a close correlation between thromboplastic and complement-fixing power of tissue extracts and serums. It seems clear, however, that complement is not identical with prothrombin, and available evidence suggests that inactivation of complement of plasma blocks the conversion of prothrombin to thrombin. The nature of the lytic action of complement is as yet, however, purely speculative.

Complement is apparently rapidly formed in the intact animal; it has been found that, following apparently complete decomplementation of the guinea pig by the inoculation of egg albumin and homologous rabbit antiserum, appreciable complement titer is detectable at eight hours and by 18 hours

has returned to normal.

Nature of complement. Complement activity is intimately associated with the serum proteins and is inactivated by enzymatic digestion. The activity is not a property of a single substance, but of more than one differentiable substance. For example, when electrolyte is removed from serum by dialysis against distilled water, the euglobulin fraction of the serum proteins is precipitated, and a part of complement activity is present in this fraction and a part in the supernatant. Neither is active alone, but when they are recombined, activity is restored. The component present in the euglobulin fraction will unite with an antigen-antibody complex but does not produce lysis, while the soluble fraction will not combine with the antigen-antibody complex but with the antigen-antibody complex plus the euglobulin fraction. Because of this, the euglobulin fraction is known as the midpiece of complement, and the other fraction as the end-piece. By a combination of various properties, complement, customarily designated C', is separable into four fractions. These are:

C'₁: This fraction is the mid-piece described above which is precipitated by dialysis, or by bubbling CO₂ through serum diluted 1:10 with distilled water. It is heat-labile and is a euglobulin containing carbohydrate.

 C_2 : This fraction is the end-piece and is also heatlabile. It is a mucoglobulin containing 10 per cent

carbohydrate.

C₃: This is a heat-stable fraction which is inactivated by treatment with cobra venom, yeast, or zymosan but is not inactivated by treatment with ammonia or pri-

mary amines.

 C_4 : This is a heat-stable fraction which is inactivated by treatment with dilute ammonia or primary amines such as hydrazine, or by shaking with chloroform or ether, but is stable to treatment with cobra venom, yeast, and zymosan. It appears to be a carbohydrate portion of the mucoglobulin fraction containing C_2 , whose carbonyl groups are attacked by ammonia.

There is evidence that C'_{3} may be resolved into two factors C'_{3a} and C'_{3b} , 64 , 89 which may participate in successive steps in the hemolysis sequence (see be-

low). 3, 63

These components of complement are found in various animals but in differing proportions. For example, C'2 and C'4 are present in only small amount in the serum of the horse, mouse, cow, and sheep; sheep serum is also deficient in C'3; and C'2 and C'3 are present in smaller amount than the other components in guinea pig and human serums. Since all four components are required for lysis, the complement titer of a serum is limited by the fraction occurring in smallest amount. Of readily available animal serums, that of the guinea pig usually shows the highest titer and is commonly used as a source of complement in serological reactions, either fresh or in lyophilized form.

The components of complement are titrated by using complement deficient in the fraction to be titrated. Such preparations are designated R'; and R'₁ is deficient in C'_1 , R'_2 in C'_2 , etc. The components tend to be functionally interchangeable to a considerable degree, as between human and guinea pig serum. On the basis of analyses of the complex, about 200 to 400 μ g. of protein per milliliter of serum combines with the antigen-antibody complex, representing the complement exclusive of C'_3

which does not combine, and the bulk of that which combines appears to be C'_1 .

Mechanism of the lytic reaction. It is already apparent from the foregoing discussion that the lytic reaction involves three components, the antigen, the antibody. and complement. This is illustrated in the accompanying schematic form for the socalled hemolytic system, i.e., that in which the antigen is the erythrocyte. The three components of the system do not react with one another at random. The antigenantibody reaction occurs first, and then complement, which does not react with either antigen or antibody alone, reacts with the complex. This may not hold true invariably, for there is evidence⁷¹ that C'₄ and C'₂ may combine with antibody alone. This may be shown in a number of ways. For example, if either antigen or antibody alone is mixed with complement, the complement activity remains free as demonstrable by appropriate titration methods (see below). Or, the antigen-antibody reaction occurs rapidly, even at O° C., but complement unites with the complex only slowly at this temperature. 50

It appears, therefore, that in immune lysis the antibody is not responsible for lysis, but rather mediates the action of complement as the lytic agent. Consequently, within this framework, antibody has been called the sensitizer, or substance sensibilisatrice, by Bordet and the French workers, and amboceptor by Ehrlich. Relatively small amounts of both antibody and complement suffice for lysis. Heidelberger has calculated that about 1500 molecules of rabbit antibody and 25,000 molecules of guinea pig complement are enough to lyse a single sheep erythrocyte. While figures such as these are no more than approximations, it is clear that only a very small part of the surface of the red cell need be affected to result in lysis.

The amount of antibody present is not a critical factor, but in regions of great excess of either antigen or antibody, lysis does not occur on the addition of complement. It is obvious that lysis will not occur if there is not enough antibody present. The failure of lysis in the presence of excess antibody is the phenomenon of complement deviation, or the Neisser-Wechsberg phenomenon, and is analogous to the prozone phenomenon in other serological reactions. The sensitizing action of antibody in the hemolytic system has a certain enzymatic character in that, in the presence of excess complement, antibody is transferred from one red cell to another, and lysis continues to occur slowly over a relatively long period.49

It is a matter of considerable interest that immune lysis may be passive. If, for example, a haptene is coupled with the erythrocyte by diazotization, or soluble antigen is adsorbed onto the surface of the red cell as in passive hemagglutination, such red cells are lysed by complement in the presence of antibody to the haptene or adsorbed antigen. Apparently, then, the combination of complement with the antigen-antibody complex in proximity to the surface of the red cell suffices to produce lysis even though the structure of the red cell is not directly involved in the initial antigen-antibody reaction. The way in which lysis occurs, in the case of the erythrocyte as leakage of the hemoglobin, is essentially unknown. On the basis of the dependence of inactivation of C'2 and C'4 by plasmin on the presence of C'₁ and calcium ions, it has been suggested46 that C'1 is a proenzyme which can be converted to an active enzyme by plasmin and the antigen-antibody complex, the latter serving as a catalyst in the activation. It is now definitely indicated the C'1 is an esterase precursor which is activated during hemolysis, but its esterase activity appears to be independent of its activity as a com-

erythrocytes + heated immune serum = no hemolysis (antigen) (amboceptor or sensitizer)

erythrocytes + heated immune serum + unheated normal serum = hemolysis (antigen) (amboceptor or sensitizer) (complement or alexin)

ponent of complement.³³ In this connection it is of interest that red cells may be sensitized to the lytic action of complement by treatment with substances such as colloidal silicic acid or tannic acid.

The reaction of complement with the sensitized cell is dependent upon the presence of both magnesium and calcium ions. In the case of lysis of sheep erythrocytes by Forssman antibody (it will be recalled that the sheep red cell contains Forssman antigen), the reaction with complement occurs in an orderly way.5 The sequence of three reactions of the several components of complement with the antigen-antibody complex, the first of which requires calcium, and the second magnesium, ions. Using the symbols E = erythrocyte, and A = antibody, this sequence is represented by 1 below. Available evidence suggests that the last step indicated may, in fact, be resolved into at least three separate reactions.24

Complement fixation.⁵⁷ Complement reacts with any antigen-antibody complex, including the precipitate from the precipitin reaction, toxin-antitoxin floccules, agglutinated bacteria, etc. When this reaction occurs, complement activity disappears in that it is no longer demonstrable in free solution, and the complement is said to be fixed. This is the complement fixation reaction or Bordet-Gengou phenomenon.

In systems in which the antigen is other than a lysable cell, there is no overt evidence that complement fixation has occurred, but the presence or absence of free, unfixed complement may be shown by the addition of an indicator system. This is a hemolytic system consisting of erythrocytes together with homologous antibody, and usually is sheep erythrocytes and homologous antiserum prepared in the rabbit. This provides the basis of the serological reaction known as the complement fixation test or reaction 2 below.

In this, as in other serological reactions, either the antigen or antibody may be unknown. If a known antiserum is used, an unknown microorganism or other antigen may be identified, and, conversely, serum may be titrated for antibody to a known antigen. This kind of serological reaction is especially useful when the antigen, known or unknown, particulate or soluble, may be difficult to prepare or obtain in purified form or in reasonably large amount, and is widely applied to viral and rickettsial antigens and antibodies.²⁶ It has been most familiar as the Wassermann test applied in the serodiagnosis of syphilis.

The question which is asked in the complement fixation reaction is the same as that asked in other serological reactions; viz., do the antigen and antibody react? If union has occurred, complement is fixed, and its activity is no longer demonstrable in the reaction mixture by the hemolytic indicator system, and hemolysis does not occur. Conversely, if the antigen and antibody do not react, there is no antigen-antibody complex to fix complement, and hemolysis occurs in the indicator system. The specificity of this serological reaction lies, then, in the initial reaction between antigen and antibody, and the indicator system is nonspecific. For example, while the sheep erythrocyte and its homologous rabbit antibody are commonly used as the indicator system, the

specificity of the complement fixation reaction would be unaffected if the rabbit erythrocyte and its homologous antibody prepared by immunization of the chicken were used.

The complement fixation reaction is technically more complex to carry out than many of the other serological reactions. It must be shown, for example, that neither the antigen nor the antibody is anticomplementary as used, i.e., that neither alone reduces the activity of added complement. Similarly, the amount of complement to be added must be determined by preliminary titration, and any residual complement activity in the serum to be tested must be removed by heat inactivation; too much or too little complement in the system will give false-negative or false-positive reactions respectively. In addition, the reagents must be added in the proper order. The antigen and antibody are allowed to react in the presence of complement for a sufficient time to allow the antigen-antibody reaction to occur and for the complex to react with, and fix, the complement. Then the indicator hemolytic system, red cells and homologous antibody, the latter also previously titrated, is added and allowed to react with any complement that may be present. Representative protocols for the complement fixation reaction and the required reagent titrations are given elsewhere (Chap. Two).

Quantitation. 42 The amount of antibody present or, conversely, the ability of the antigen to react with the antibody, may be approximated by carrying out the complement fixation reaction with serial dilutions of the antiserum. It may be made more precisely quantitative by determining how much complement is fixed by the antigen-antibody complex. This is carried out by adding a precisely known excess of complement and backtitrating the unfixed complement with the hemolytic system.

The reaction is read as the amount of hemolysis and is inverse, in that hemolysis is indicative of a negative antigen-antibody reaction. The end point may be taken as complete hemolysis, designated as ++++, and varying degrees of hemolysis as +, ++, or +++. The inverse relationship appears when no hemolysis is recorded as a ++++ antigen-antibody reaction, + hemolysis as +++ antigen-antibody reaction, etc. While

this relatively crude criterion is sufficient for many purposes, the end point of complete hemolysis is subject to the same fallacy as a 100 per cent killing of microorganisms by a disinfectant (Chap. Six) or a 100 per cent mortality as an assay of virulence of toxicity (Chap. Nine); i.e., the sensitivity of erythrocytes to lysis is approximately normally distributed and 100 per cent lysis is a limit approached asymptotically. A more precise measure of hemolysis is, then, an interpolated 50 per cent end point from observed fractional hemolysis assayed photometrically.

OPSONINS

If a mixture of polymorphonuclear leucocytes and bacteria or other particulate matter is incubated for a time, it will be found on microscopic examination that a number of the leucocytes have ingested the foreign particles. Few if any particles will be ingested if the mixture is prepared in physiological salt solution, a considerable number if the fluid is normal serum. In the case of bacteria, great numbers of the microorganisms will be found packed into the leucocytes when the two are suspended in the specific immune serum. The antibodies present in the immune serum which so remarkably stimulate this engulfment by body cells are designated bacteriotropins, a term not in common use, or opsonins. The term

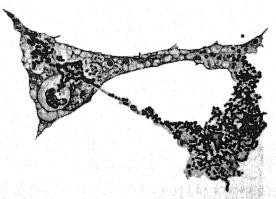

Figure 77. Phagocytosis of pneumococci by culture macrophages. The lightly staining pneumococci are degenerating. Hematoxylin and eosin-azure II. \times 1200. (Zuckerman.)

opsonin was originally used to designate the activity of normal serum; hence the antibodies in the immune animal are sometimes called immune opsonins. The cells which ingest such particulate matter are termed phagocytes. This property is not confined to the polymorphonuclear leucocytes or heterophils, although these have been most widely used in in vitro experiments because of their availability, but is also present in mononuclear phagocytes, circulating and fixed tissue cells, or histiocytes, demonstrable in the latter by, for example, perfusion of isolated organs as well as in vivo.39 These cells and their role in immunity are discussed in the following chapter.

The opsonic index. A quantitative estimate of opsonin present in a given immune serum may be made by comparing the number of bacteria ingested by normal leucocytes in normal serum with the number ingested by normal leucocytes in the immune serum. The appropriate mixtures are prepared and incubated in capillary tubes, smears made and stained, and the bacteria engulfed by an arbitrary number (usually 50 or 100) of leucocytes counted. The average number of bacteria per leucocyte, or phagocytic index, is determined for the normal and immune serums, and the ratio of the phagocytic index of the immune serum to that of the normal serum is termed the opsonic index.

The opsonins may be estimated also by the dilution method; specimens are prepared in the usual way, except that the normal and patient's serums are diluted with saline or Ringer's solution. One mixture is made with salt solution or Ringer's solution to determine the degree of spontaneous phagocytosis. The dilution of serum which gives the same amount of phagocytosis as a mixture without serum is taken as the end point.

The factors influencing phagocytosis.³⁷ The process of phagocytosis is markedly influenced by environmental factors and the nature of the bacterium and leucocytes used, as well as by the amount of opsonin present. Departures from a neutral or very slightly acid reaction or from isotonicity, and the presence of certain ions, notably the citrate radical, depress the degree of phagocytosis. The last is of practical significance in that it contraindicates the use of citrated blood.

The presence of calcium, on the other hand, may restore phagocytic power to leucocytes which have been allowed to stand in isotonic salt solution for a number of hours, a point of some interest in connection with the apparent intimate relation between this ion and cell division and the ability of ameboid cells to form new surfaces.

The nature of the bacterium to be ingested is of considerable importance; in general, virulent forms are relatively resistant to phagocytosis. It is not unlikely that this resistance is associated with the presence of a capsule; in the case of the pneumococcus, for example, not only are the smooth, encapsulated forms highly resistant to phagocytosis, but the presence of capsular polysaccharide markedly inhibits phagocytosis by an immune serum, 35, 67 presumably through combination with the antibody. Bacteriophage renders bacteria considerably more sensitive to phagocytosis.

The phagocytic power or activity of the leucocytes is subject to considerable variation independent of variation in the opsonic content of the blood. This inherent phagocytic power of the leucocytes varies, with respect to certain bacteria at least, even in persons apparently in perfect health. In the child at birth the leucocytes are somewhat less active phagocytically than in the adult; they grow less active for a few months, and then more active, reaching the adult standard for streptococci, pneumococci, and staphylococci about the third year. In pneumonia, scarlet fever, and other conditions in which there is acute leucocytosis when the outlook is favorable, the phagocytic power of leucocytes has been found to be greater than normal for the specific bacteria. The increase in activity in such cases may be due to the predominance of young leucocytes.

The process of phagocytosis. The mechanism of ingestion is essentially one of the interplay of interfacial forces. Low interfacial tension of the bacteria against the leucocytes—and high interfacial tension against the medium—favors ingestion. The immune opsonins, and to some extent the "normal" opsonins, apparently form a surface deposit on the bacterial cells which promotes phagocytosis by altering the interfacial tension in this manner. In addition to surface tension, other factors such as the viscosity of the phagocytic cell substance enter into this phenomenon. Physical forces

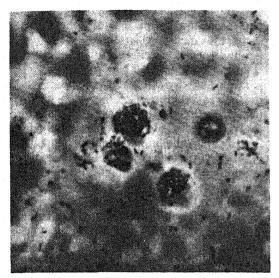

Figure 78. The phagocytosis of typhoid bacilli by leucocytes in whole blood. Note the enormous numbers ingested by the white cells and the bacilli lying free. Hastings' stain; \times 1200.

are not the sole controlling factors, however, for increased oxygen consumption accompanies the process of ingestion, the rise beginning at once, reaching a maximum value twice that at the start in about 15 minutes and persisting for 90 to 150 minutes. It has been suggested that the accumulation of hydrogen peroxide may contribute to the killing of phagocytosed bacteria.⁴⁰

It is of some interest that bacterial cells may be artificially "opsonized," i.e., made more readily phagocytable, by treatment with iron ammonium alum, chrome alum, protamine sulfate, or gallotannic acid. The effect is reversed by treatment with oxalate, but reversion is very difficult when the cells are sensitized with immune opsonin. The significance of such observations in immune opsonization and phagocytosis is not clear.

Phagocytosis may occur quite as readily in the absence of antibody as in its presence, provided that it occurs on a suitable surface; most body tissues provide such surfaces, viz., the phagocytosis of pneumococci on the alveolar surfaces of the lungs. This is the phenomenon of surface phagocytosis.⁷³

The fate of ingested bacteria. Following phagocytosis many, but not all, species of bacteria may be observed to undergo a process of dissolution, with swelling, granulation, and fragmentation appearing as successive stages in their destruction. Although it was early supposed that intracellular

digestion was no more than intracellular lysis through the agency of the immune lysin and complement which would have occurred whether or not phagocytosis took place, it now seems probable that the two processes are essentially different.

Bacteria are no exception to the rule that living organisms are not subject to attack by digestive enzymes, and the question arises whether death is a necessary preliminary to ingestion or whether it may occur within the phagocyte. It is probable that the viability of the microorganism is not an important factor in phagocytosis; in most cases the cell may be engulfed whether it is living or dead. In the case of those bacteria which are destroyed within the leucocyte, killing is necessary before digestion can take place.

Bactericidal agents are present within the phagocytic cells, but are not equally effective on all kinds of microorganisms; in some instances at least their activity appears to be potentiated by antibody.28,65 Such substances are designated leukins in the older literature; one, or a group, of these has been studied intensively and named phagocytin.³⁶ Others appear to be lysozymelike in nature. 62 The efficacy of the killing process in the case of susceptible microorganisms is illustrated in observations⁷² on avirulent streptococci, more than 90 per cent of which are destroyed in 15 minutes within the phagocytic cell. When these substances are not effective, the infected phagocytic cells serve to protect the microorganism from antibody²⁸ and may serve to disseminate the infection. Influenza virus, for example, is phagocytosed but remains infective for extended periods,7,34,43 and in general virulent bacteria such as streptococci tend to persist and may destroy the phagocyte.

Leucocytes have been shown to contain a variety of digestive enzymes, including proteases, lipases, and various carbohydratesplitting ferments which are presumably responsible for the actual dissolution of the engulfed particle.

The nature of the opsonic activity. The opsonins are true antibodies in that they are increased by immunization and exhibit the specificity characteristic of the immune antibodies. The activity is, like that of the lytic serums, made up of two components, one thermostable and the other thermolabile. The thermolabile component is pres-

ent in normal serum, and the reduced opsonic powers of an inactivated immune serum may be restored by the addition of a small amount of normal serum. In this and other respects the thermolabile component of opsonin strikingly resembles complement and in the past has been assumed by many to be identical with this component of the lytic system. In general, however, it has not been possible to show any constant relation between the components of complement and opsonization. For example, while the fourth component of complement has been reported to be necessary to the lytic reaction but not required for opsonization, it has also been observed that the thermolabile opsonin of the human serum is identical with C'1, C'2, and C'4 in combination but not separately or in any combination of two. It appears, then, that the complement and the thermolabile element of opsonin, while resembling each other closely in many respects, may not be regarded as identical.

PROTECTIVE AND NEUTRALIZING ANTIBODIES

When an antigen is a pathogenic microorganism, or a toxic product of a microorganism, antibody to it may protect a susceptible animal against infection or the effects of a toxic substance. Assay of this kind of antibody activity has been referred to earlier in connection with the standardization of antitoxins but is more widely applicable than indicated there.

The measurement of such antibody activity is dependent upon establishing a point of reference, such as the LD_{50} dose of microorganisms or toxic substance in the normal animal, and comparing with it a similar value obtained in the presence of antibody. In practice the challenge inoculum is ordinarily a multiple of the LD_{50} and, for sound mathematical reasons, is held constant while the amount of antibody is varied.

The observed protective or neutralizing effect may be attributed to opsonic, lytic, antitoxic, and other antibody activities, and does not distinguish among them. At the same time, it measures the contribution of the antibody, and inferentially the antigen preparation, to effective immunity and thereby differs from the *in vitro* serological reactions. Such tests of antibody activity are

of two general kinds, the protection test and the neutralization test, and the antibody activity so measured is said to be protective antibody or neutralizing antibody.

Protection tests. The protection test is in turn subdivided into two kinds of tests, the active protection test and the passive protection test, depending upon whether the test animal forms its own antibody in response to the inoculation of an antigen or is the passive recipient of preformed antibody from another animal.

Active protection and immunogenic potency. The active protection test is a test of immunogenic potency of the antigen. It is carried out by inoculating groups of animals with serial dilutions of antigen, or a number, usually a fairly large number, of animals with a specified dose of antigen. The former is required for most kinds of experimental studies, and the latter is often used for the routine assay of the immunogenic potency of vaccines prepared and distributed commercially.

After a time, such as one to three weeks, during which the immune response develops, the animals are challenged with some standard dose, say 1000 LD_{50} , of the virulent microorganism of the toxin. The protection conferred by immunization is measured as the amount of antigen required to protect 50 per cent, or some other specified portion, of the animals inoculated.

Since the details of this and other kinds of protection and neutralization tests are determined by the kind of microorganism or toxin used for immunization and subsequent challenge, such tests can be described in only general terms. At the same time, two points must be taken into consideration in tests of this kind. First, the susceptibility of the normal experimental animal, commonly the mouse, should be known to be reasonably constant, and animals of at least pen-bred homogeneity are usually required. Second, the microorganism must have relatively high virulence for the experimental animal for, when large doses must be used, those of living microorganisms required to kill may approach the toxicity level, i.e., the lethal dose of killed microorganisms. This is generally true, for instance, in the case of the enteric bacilli, the gonococcus. the meningococcus, and certain other kinds of bacteria. The relative virulence of the microorganism thus affects the level of protection found; usually very high titer of protective antibody, of active or passive origin, is not observed when the microorganism is relatively avirulent.

Further, the relation of the experimental infection to the naturally occurring human disease needs to be taken into consideration when such experimentally determined immunogenic potency is used to characterize antigens intended for human use. For example, the virulence of the cholera vibrio for the mouse is very low, but may be greatly increased by suspending the bacteria in mucin to give a fatal fulminating bacteremic infection on intraperitoneal inoculation with perhaps 100 vibrios. The usual test for immunogenic potency of cholera vaccines is carried out in the mouse, but it is not clear what relation the challenge infection may have to the naturally occurring human infection in which the microorganisms are confined, for all practical purposes, to the lumen of the bowel and, therefore, to what extent immunogenic potency so measured is applicable to man. Similarly, the challenge inoculum of pertussis bacilli for testing active protection in mice is given intracerebrally. The infection would seem to be quite unrelated to whooping cough in man, but it is significant that protection of mice against infection by this route parallels that against infection by the intranasal route which produces an infection in mice similar to that observed in man.

Passive protection. In the passive protection test, antiserum is tested for protective antibody by parenteral inoculation of groups of animals with graded doses in constant volume. Some time may be allowed to elapse between the administration of antiserum and challenge inoculation, six to 24 hours, so that the antibody is absorbed by the tissues of the animal. Or, if given nearly simultaneously, antiserum and challenge inoculation may be given by different routes, such as subcutaneously and intraperitoneally respectively. In any case, the passively immunized animals are challenged with some standard dose of the infectious agent or its products. The LD₅₀ dose is interpolated in the usual way and, by comparison with the LD₅₀ dose in the normal animal and the amount of antiserum required to protect 50 per cent of the immunized animals, the number of LD₅₀ doses protected against by 1 ml. of antiserum, or its protective antibody titer, is readily calculated.

Neutralization tests. The neutralization

test is usually used in the neutralization of toxin by antitoxin and for the titration of antibody concerned in immunity to viral infections.23,47 It differs from the protection test in that varied amounts of antiserum are mixed with a standard dose of microorganisms or toxin, allowed to stand for a period, such as 30 minutes, to permit the antibody present to react with the antigen, and the mixture is then titrated for infectivity or toxicity. The assay may, of course, be carried out in the intact animal, but it is also applicable to tissue culture or egg culture while the protection type of test is not. The assay criterion is the death, or other effect, of 50 per cent of animals, tissue cultures, egg cultures, etc., and the titer of neutralizing antibody is calculated in the same way that protective antibody titer is calculated in the passive protection test.

Chapter Fifteen

THE IMMUNE STATE

Immunity to disease, or effective immunity operative in the specific immune state, is to be distinguished from the immune response in the technical sense on the one hand, and from resistance, sometimes called natural immunity or innate immunity, on the other. In the first instance, not all antigens provoke the formation of protective antibody. This is obvious in the case of antigens, such as ovalbumin, which are unrelated to pathogenic microorganisms or their products. Further, as implied elsewhere (Chap. Twelve), not all the components of the complex of antigens making up the antigenic structure of a microorganism are concerned in effective immunity to the disease which it causes. Among the enteric bacilli, for example, antibody to the heatlabile antigens is apparently quite unrelated to effective immunity, and only antibody to the heat-stable antigens is protective.

Distinction between specific acquired immunity to disease and resistance or natural immunity is usually made on the basis of specificity; *i.e.*, acquired immunity is functional only against a specific microorganism, or sometimes a group of immuno-

logically related microorganisms, while in natural immunity there is no distinction on the basis of antigenic specificity. The separation of acquired and natural immunity often cannot be made as sharply as implied. It is complicated by the common, practically universal, occurrence of so-called natural antibody, and the cellular response of acquired immunity differs quantitatively rather than qualitatively from that occurring in the normal animal.

The state of immunity to disease is separable into two parts: that which is primarily dependent upon the presence and activity of circulating antibody, humoral immunity; and cellular immunity, which is a function of the activity of phagocytic cells and the cellular response in the processes of inflammation. These parts also merge with one another, most obviously in the opsonic activity of antibody, in the function of cells in the synthesis of antibody in response to antigenic stimulus, and in the predominantly cell and tissue response of hypersensitivity mediated by antibody. Nevertheless, such a separation is useful for purposes of discussion.

Humoral Immunity

The appearance of circulating antibody during recovery from infectious disease, and its association with the refractory state of specific acquired immunity, suggests that it may be causally related to effective immunity. The significance of antibody to effective immunity is firmly established by the kind of experimental evidence which provides the basis of the passive protection and neutralization tests (Chap. Fourteen). Less direct, but highly suggestive, evidence

of the significance of circulating antibody in effective immunity is the high susceptibility to infection of individuals who fail to form γ-globulin. Congenital agammaglobulinemia, which may have a hereditary basis, has been observed in a number of instances³³ associated with susceptibility to generalized vaccinia and pyogenic infection. In general, it may be stated categorically that, so far as is known, acquired effective immunity rests upon an antigen-antibody basis.

Antitoxic immunity. The function of various kinds of antibody activity in effective immunity is a matter that becomes partly speculative. As in the case of virulence of pathogenic microorganisms when virulence is attributable to essentially a single factor, such as toxigenicity and the pharmacological activity of the bacterial exotoxins, the nature of effective immunity to such a disease is equally clear. In tetanus and diphtheria, for example, the single significant factor in acquired immunity is antitoxin, and antibody to the cell substance of the causative microorganism is, at most, of only minor importance.

In the case of other soluble toxic products of pathogenic microorganisms, differentiation of the effective from the plausible function of antibody may be resolved to some extent by the protection test. The gaseous gangrene microorganism, Clostridium welchii type A, for example, produces three welldefined toxic products: the hemolytic α and θ toxins, and the κ toxin or collagenase. It might be supposed that collagenase activity would be a highly significant factor in a disease characterized by extensive tissue destruction and that antibody to it would be functional in effective immunity. This has not proved to be true, for antibody to the α toxin is protective while those to the other two toxins are not.

Or, antibody may affect the character of the disease but not otherwise materially modify its severity or prevent it. Scarlet fever is a clinical entity only because of the activity of the erythrogenic toxin, and antibody to this toxin prevents the appearance of the scarlatiniform rash, but contributes little or nothing to immunity to infection with the causative streptococci.

Antibacterial activity. The function of antibody having other than antitoxic activity is less clear. The phagocytosis of microorganisms is a highly significant feature of immunity to infections with a variety of bacteria, such as the staphylococci, and it is highly probable that the opsonic activity of antibody plays an important part in effective immunity. In some instances, though, simple phagocytosis mediated, or accelerated, by circulating antibody may serve to protect the microorganism or even facilitate the spread of infection. Brucellosis, for example, persists in spite of high circulating antibody titer, and the inadequacy of the

immune response, together with the limited effectiveness of chemotherapeutic drugs in this disease, is thought to be a result of persistence of the microorganism within host cells.

Agglutinins and precipitins would appear on the surface to serve no useful purpose in the defenses of the immune animal; for example, bacteria are not killed by agglutination. The clumping of bacteria and the precipitation of soluble foreign protein, however, considerably facilitate the process of phagocytosis, in that many bacteria may be engulfed at one time and insoluble masses of precipitated foreign protein may thus be removed. In the case of pneumococcus antiserums, for example, protective antibody as measured by mouse assay appears to be identical with precipitin and agglutinin. The pneumococcus antibody has been found to enter pneumonic lesions in rats, agglutinating the free pneumococci in the alveoli and thus stopping the spread of the infection.

In the absence of complement, microorganisms are not killed by antibody, and the not uncommon limited therapeutic effect of extremely high titer antibacterial serum has been regarded as an expression of the lack of sufficient complement to take full advantage of the large amounts of antibody present. The bactericidal and lytic activity of complement mediated by antibody probably contributes significantly to effective immunity to at least some kinds of infections.

In some instances antibody may inhibit the reproduction of microorganisms. It was first suggested that antibody might function as an ablastin in pneumococcal infections, with suppression of proteolytic and glycolytic activity, but the evidence in this and other bacterial infections is inconclusive. In general, respiration is not affected by the presence of antibody, and an observed stationary microbial population may occur because the rate of reproduction is balanced by the death rate or because the microorganisms survive but do not multiply.

A reproduction-inhibiting effect of antibody has been demonstrated conclusively only in the case of the protozoan *Trypano*soma lewisi where it is possible to differentiate between lytic activity and inhibition of cell division as attributable to different antibodies. A possibly similar mechanism is operative against the relapsing fever spirochetes (Chap. Thirty-three), but this is not conclusively established. Otherwise there is little evidence that inhibition of reproduction of the microorganism is a significant element in effective immunity.

Essential immunizing antigens. relatively greater importance of antibody to some kinds of toxic substances to effective immunity may be expanded somewhat further. Antimicrobial antibody to various differentiable portions of the antigenic mosaic also vary widely in their contribution to effective immunity. In the case of pneumococcus, antibody to the capsular substance, i.e., type-specific antibody. is primarily concerned in effective immunity to infection, while the contribution of antibody to the somatic antigen is relatively unimportant. In infection with this microorganism phagocytosis is a significant element of the defense mechanism, and the marked association between virulence of the pneumococcus and the presence of a capsule is a consequence of inhibition of phagocytosis by the capsule. Coating of the encapsulated bacteria with antibody facilitates phagocytosis so that antibody to the capsular substance is of primary importance to effective immunity. Or, in the case of streptococcal infection, antibody to the typespecific M antigen, which appears to be very superficially located on the cell, is of greatest importance to effective immunity, while that to the type-specific T antigen and to the group-specific C substance is of lesser importance. In the case of the enteric bacilli and the cholera vibrio, effective immunity is associated with antibody to the heat-stable somatic O antigen and that to the heatlabile H or flagellar antigen is not protective.96

In some instances the antigenic complex that stimulates the formation of protective

antibody may be broken down further. As indicated elsewhere, the typhoid bacillus exists in two forms, the V form which contains Vi antigen, and the W form which does not. Vi-containing strains which lack typhoid bacillus O antigen can be obtained by dissociation, and certain other bacteria, notably a widely used strain of Salmonella ballerup, contain Vi antigen but are unrelated to the typhoid bacillus with regard to the specificity of the O antigen. Immunization with Vi-containing bacteria which lack the typhoid bacillus O antigen, whether typhoid bacilli or not, will protect against infection with V strains of the typhoid bacillus but not against infection with W strains. Conversely, immunization with a W strain of the typhoid bacillus will protect against infection with either V or W forms of this organism, but not against infection with Vicontaining bacteria that lack the O antigen of the infecting strain. It is concluded, therefore, that antibody to the O antigen and that to the Vi antigen are concerned in protection. The components of the other O antigenic complexes occurring in the Salmonella group are not sharply differentiated, in that all seem to contribute to an effective immunity.

The antigens so related to the effective immune response are sometimes spoken of as "essential immunizing antigens." It follows, of course, that not only should an effective immunizing preparation contain the significant antigens, but antigens extraneous to the development of an effective immunity may be omitted. The first consideration has indicated the use of typhoid vaccine prepared from Vi-containing strains, and the second is the basis of the endotoxoid vaccines such as those from the plague bacillus.

Cellular Immunity

The cells of the body have two major roles in immunity to disease, the phagocytosis of microorganisms and other particulate material, and the formation of antibody. The former was established by Metchnikoff at the turn of the century, working first with the water flea, Daphnia, and then with mammalian cells. He differentiated two kinds of

phagocytic cells, the microphages or polymorphonuclear leucocytes, and the macrophages or large mononuclear cells occurring both free and as fixed tissue cells. Although their immediate mobilization accentuates the limited significance of the polymorphonuclear leucocytes, the variety of fixed and free connective tissue cells of mesenchymal

origin, grouped under the general head of macrophage, is of considerably greater importance in resistance to disease.

The distribution and interrelationships of these phagocytic cells may be described

briefly in outline form:6, 90, 91

(A) The predominantly fixed cells of the reticular and loose connective tissue which can be divided into two great groups: (1) fixed and free macrophages. including the reticular cells and (2) the fibroblasts of connective tissue and the endothelial cells lining the ordinary blood vessels.

(1) Macrophage is essentially a physiological designation for almost any large mononuclear connective tissue cell which is predominantly

phagocytic and includes

(a) Fixed cells such as

1. Pericytes (Maximov), fixed, undifferentiated outstretched cells in the adventitia of all the small blood vessels of loose connective tissue throughout the body

2. Reticular cells which, with fibers, form the stroma of all reticular (myeloid and lympathatic) tissues

3. Littoral cells (Siegmund) which line the sinuses of the reticular tissues, liver, hypophysis, and adrenals. In the liver these are designated as Kupffer cells. Although frequently called endothelial cells or cells of the special endothelium, these are in fact either true reticular cells or have greater developmental potencies than ordinary endothelial cells.

These cells can divide by mitosis, become phagocytic, and develop into fibroblasts or practically any other blood or connective tissue cell. Here it is important that they can become phagocytic either in their fixed position (fixed macrophages) or after rounding up and becoming free (free

macrophages).

(b) The free cells occurring in the loose connective tissue are variously known as histiocytes, clasmatocytes, rhagiocrine cells, or wandering resting cells, are either phagocytic or can become so without morphological change, can reproduce by mitosis, and transform into fibroblasts.

(2) The fibroblasts and endothelial cells are morphologically characterized by outstretched, ill-defined cytoplasm, a large oval vesicular nucleus containing dust-like chromatin granules, and small nucleoli.

(a) The fibroblasts divide by mitosis but do not develop into other cells (except in bone and cartilage) and are rarely phagocytic although instrumental in repair

and walling off foreign material. (b) The endothelial cells which line the larger

blood vessels and capillaries (not including the littoral cells) likewise are rarely phagocytic but may be transformed into fibroblasts.

(B) The free connective tissue and blood cells.

(1) The cells of the blood and lymph are classified as to whether of myeloid or lymphoid origin:

(a) The lymphoid cells of the blood include the various sized lymphocytes which, together with monocytes, are termed agranulocytes. They divide mitotically and can develop into macrophages with all the latter's developmental potencies. As they become transformed into macrophages, they show increased amounts of cytoplasm, their nuclei take on macrophage characteristics, and they become phagocytic. These transitional forms are known as polyblasts.

(b) The myeloid cells are the various granulocytes (heterophils or polymorphonuclears, eosinophils, and basophils), the erythrocytes, and platelets. Of these the heterophils are functional in immunity by virtue of their phagocytic activity but are "end" cells which do not reproduce or develop into other cells.

(2) The free mesenchymal cells are lymphoid cells indistinguishable from lymphocytes which occur in varying numbers in reticular and loose connective tissue and here act as precursors or "stem" cells of lymphoid and myeloid cells and hence may give rise to macrophages. They are variously termed lymphocytes, hemocytoblasts, lymphoblasts, myeloblasts, or monoblasts according to varying theories of blood formation. Under normal conditions lymphocytes in lymphatic tissue give rise only to lymphocytes, and hemocytoblasts in bone marrow only to myeloid cells, but under abnormal stimuli they may exhibit their full potencies for development. These stem cells are self-perpetuating, but as noted above, may arise from the fixed mesenchymal cells.

The systems of cells. It will be apparent that the cells primarily associated with defense against invading microorganisms are widely distributed through the body in the blood and lymph, cartilage, bone, reticular (blood-forming) tissue of the myeloid and lymphatic organs, and in the loose connective tissue associated with the skin, omentum, liver, lung, etc. It is customary to group the macrophages into so-called systems of cells. Metchnikoff's macrophage system includes the fixed tissue macrophages and the free macrophages and monocytes of the blood together with the various transitional forms, or polyblasts. Aschoff groups the cells concerned in defense as the reticuloendothelial system (RES) which, in the broad sense, includes the various fixed tissue macrophages and the free macrophages occurring in the inflammatory process. This term is unfortunate in that endothelial cells are not phagocytic, and the reference is to the so-called special endothelium such as littoral cells. The most all-inclusive term is the lymphoid-macrophage system which covers also the lymphoid cells which, as stem cells, may be transformed into macrophages.

to an inflammatory stimulus is characterized by an initial migration of polymorphonuclear leucocytes to the point of injury. These cells are not numerous and soon disappear when the inflammatory material is sterile, but when bacteria are present they continue to migrate from the blood vessels and actively phagocytose the invading microorganisms. The functions of this first line of defense, although important, are strictly limited, since the cells are short-lived and do not multiply *in situ* but must be continuously recruited from the blood stream.

More important to local defense are the lymphoid cells of the blood and lymph, the lymphocytes and monocytes, which also migrate from the blood vessels but which, unlike the polymorphonuclear leucocytes, are long-lived and multiply in the tissues. These stem cells may be transformed to macrophages which, together with macrophages already present in the area, actively phagocytose and digest the invading microorganisms. When large bodies of foreign material are present, the macrophages may fuse to form foreign body giant cells; when microorganisms are indigestible they may form giant cells around them such as the epithelioid cells of the tubercle. Their progressive development into fibroblasts supplies the active elements for regeneration and repair, the formation of scar tissue and the walling off of foreign bodies.

Certain other cells may take part in the late stages of the inflammatory process; the eosinophils, for example, may play a part in the detoxification of proteins and their disintegration products.

The inflammatory reaction 40. 55. 80. 92 plays an important part in eliciting this cellular response and contributes to the tissue injury produced. A polypeptide, designated leucotaxine, which is found in exudate fluid, increases capillary permeability and provides a chemotatic stimulus for the early heterophil migration; its activity is antagonized to some extent by substances such as cortisone and hydrocortisone. A leucocytosis-promoting factor of pseudoglobulin

nature, found in the α -globulin fraction of exudate, is also produced in the inflammatory process that is associated with hyperplasia of granulocyte precursors in the bone marrow. A leucopenic factor, of polypeptide nature, is formed also, together with a toxic euglobulin called necrosin. The latter is absorbed from the inflammatory lesion, possibly producing injury elsewhere, especially in the liver and kidneys. This last is an example of a toxic substance of host rather than microbial origin as described elsewhere (Chap. Nine).

General defense. When a stimulant is distributed over a large part of the body the reaction is regarded as a general rather than local one; such distribution, however, usually means that the stimulant is in the blood stream and is combated by the cells of organs most closely associated with the blood, i.e., the spleen, liver, and bone marrow, and in some cases general reactions may be regarded as local ones in strategically placed organs.16 The same types of cells are involved as in the local reaction. the polymorphonuclear leucocytes being mobilized first, with the macrophages playing the more important role. Endothelial cells, although in contact with bloodborne material, show very little phagocytic activity, and the fibroblasts are rarely active.

The cellular response in immunity. 23, 45 The above reactions, which are observed to occur in the nonimmune animal, are markedly accentuated in the immune animal, and there is an increase in the number of macrophages frequently designated as a hyperplasia of the reticuloendothelial system. The cooperative role of the humoral antibodies is of considerable significance: 102 an antigen is localized by agglutination if cellular or by precipitation if in solution, and in either case the material is made more readily phagocytable by opsonization. Bacteria injected into the blood stream, for example, are rapidly removed in the immune animal by the fixed macrophages of the liver and spleen,73 and staphylococci injected into the skin are localized and phagocytosed in great numbers. When antigen and antibody meet in the tissues of an immune animal, there are not only localization and opsonization of the antigen, but also a much heightened inflammatory reaction including a speeding up of the cellular response.

SITES OF ANTIBODY FORMATION^{54, 63, 87}

Although antibody is ordinarily titrated and studied as it occurs in serum, serum antibody represents that synthesized by cells and spilled over into blood and body fluids. The function of cells in the synthesis of immune globulin is inferred from several lines of evidence, including interference with antibody formation by inhibition, removal or destruction of certain tissues, antibody production by transplanted cells, the distribution of antibody activity within the tissues, and the cytological events coinciding with antibody formation. While it is believed by some that both normal and immune globulin are synthesized in the same way, antibody resulting from a deviation in the normal synthetic processes, it does not necessarily follow that conclusions regarding the synthesis of immune globulin are completely applicable to the processes of synthesis of normal serum protein.

The relation of cells of the macrophage system to antibody formation is indicated by the results of interfering with their function. Blockade, by the inoculation of relatively large amounts of particulate material, such as carbon particles, so that all the phagocytic cells are packed with the substance and phagocytosis is sharply inhibited, markedly reduces the immune response. Similarly, removal of tissue rich in the elements of the macrophage system, as by splenectomy, also markedly modifies the the formation of antibody.

Gross injury to the cells of myeloid, as well as lymphoid, origin by ionizing radiation also affects antibody formation. When administered prior to, or within a short time after, the inoculation of antigen, irradiation sharply reduces or even eliminates the immune response, although a pre-existing immune response is not affected. The effect of lethal, or near-lethal, whole body x-irradiation is so marked that the homograft reaction disappears. Lethal doses of ionizing radiation destroy the bone marrow, and substantial protection is conferred by inoculation of the treated animal with bone marrow from normal animals. The irradiated animal does not give a homograft reaction to the transplanted cells, and, although they are eventually replaced when the animal survives, they persist and multiply with the appearance of blood cells of myeloid origin characteristic of the donor to give a radiation chimera. Irradiated animals similarly do not react to skin, tumor, and other tissue grafts.

Antibody formation in vitro.93 If cells are primarily responsible for antibody formation, it should follow that such cells would form antibody in tissue culture. It is well established that explants of lymphoid tissue from immunized animals,82 i.e., the cultured cells, are already committed to the immune response.83 The induction of antibody formation in similar cultures of cells from normal animals was reported as early as 1912, but for many years the results could not be repeated. More recently, a number of reports of the induction of the antibody response by normal cells in culture in response to antigenic stimulus have appeared. 11, 32, 58 It is not altogether clear what conditions are required. Positive results have been obtained by the inclusion of RNA, apparently of the mRNA type, from immunized animals in the cell culture,14,28,52 but this would appear to be a case of adoptive immunity (see below). The initiation of antibody synthesis in vitro in paired explants of spleen and thymus⁷⁶ is of interest in connection with the apparent significance of the thymus to the immune response (see below).

Cell-mediated antibody formation.¹³ Explants of lymphoid tissue from immunized animals will also form antibody in vivo, i.e., when inoculated into a normal animal.⁸⁶ This occurs even when the recipient, such as the immature or irradiated animal, is unable to form antibody, or as in the case of the appearance of antibody to the typhoid bacillus in an individual having agammaglobulinemia but receiving lymphoid tissue from an individual immunized with typhoid vaccine.

Further, hypersensitivity of the delayed type (see below), which is not passively transferable by serum, may be transferred by the inoculation of a normal animal with lymphoid tissue from a sensitized animal. The occurrence of an immune response mediated by cells adds a third facet to acquired immunity which has been called "adoptive" immunity.^{5, 17, 59}

Antibody-forming cells. The association of antibody formation with lymphoid tissue is of long standing, and there is an impressive amount of evidence in the immune

response of the intact animal supporting it. For example, a number of workers, including Erich and his co-workers and Harris and his co-workers, have carried out the kind of experiment in which minimal amounts of antigen are inoculated into the footpad of an experimental animal, usually the rabbit, and the afferent and efferent lymph from the regional lymph nodes examined for antibody activity. This kind of experiment is subject to control by giving different antigens on either side of the animal and titrating the lymph specimens for both kinds of antibody activity. In such experiments much more antibody to the locally inoculated antigen is found in the lymph draining from the node, the greater part of which is found contained in the lymphocytes. Such evidence is clearly indicative of the ability of lymphoid cells, but not necessarily mature lymphocytes, to form antibody.

In the same vein, the role of various organs in antibody formation may be examined. This is necessarily indirect because antibody-forming tissues apparently do not retain antibody. The importance of the spleen, for example, is indicated by the

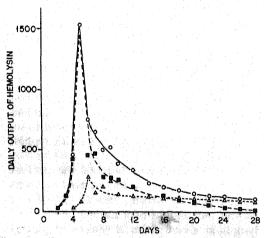

Figure 79. The mean daily output (not serum titer) of hemolytic antibody to the sheep erythrocyte by the rabbit following a single intravenous inoculation of antigen. The total output by the intact animal (circles), the nonsplenic output (triangles) by splenectomized animals, and the splenic output (squares) by difference are shown. Note the high peak and precipitous decline in splenic antibody output and the lower peak but continued production of nonsplenic antibody. (Taliaferro.)

relatively large amounts of antibody formed in tissue culture by explants from immunized animals, but the red pulp is more active than the follicular tissue.

The cytological evidence for the formation of antibody by cells is the localization of antigen and antibody within cells, and the cell types and changes associated with antibody formation.24 In the first instance, labeled antigens, viz., coupled dye-proteins and antigens containing I¹²⁷ or I¹³¹, or S³⁵, may be used, or antigen may be located by treatment of the cells with fluorescent antibody. Similarly, antibody may be located within cells by treatment with fluorescent antigen. Studies of this kind have shown that antigen is found in phagocytic cells of the macrophage system, but that antibody is found, not in the same cells as antigen, but in plasma cells or immature plasma cells whose active nucleic acid synthesis is shown by their affinity for methyl green-pyronine. Such cells also appear in cell cultures of explants from immune animals on secondary antigenic stimulus in culture.72

In a general way, the immune response, especially the secondary or anamnestic response, is characterized by hyperplasia of the lymphoid-macrophage system. More precise studies have shown that the antibody response is associated with the occurrence of the large pyroninophilic cells found to contain antibody. For example, in their studies on the rabbit lymph node, Leduc, Coons, and Connolly⁴⁸ found relatively few of these cells in the normal animal, but on antigenic stimulation larger numbers appeared in the medullary portion of the node, multiplied and differentiated, and accumulated increasing quantities of antibody in the cytoplasm until the development of the cells reached a point at which they appeared to be mature plasma cells. The primary and secondary immune responses were similar, but many more antibodycontaining cells were found in the anamnestic reaction. A similar cellular response, but without identification of intracellular antibody, was observed in the spleen explants noted above, the red pulp explants containing large numbers of similar cells, described as "transitional," and the follicular tissue explants very few.41

Antibody formation by single cells. 61 It has been found that single lymphoid cells,

taken from an animal immunized with more than one antigen, form antibody to one or another of the immunizing antigens; i.e., individual cells form antibody of a single specificity and the observed multiple antibody response is apparently attributable to the pooling of the antibody output of many cells. This is apparently not invariably true. for the formation of antibodies of different specificities by single cells has been described,2 but the proportion of such cells appears to be very small.62 Formation of antibody by single cells may be observed as an agglutination of the bacterial antigen by antibody secreted by a single cell in an aqueous droplet in paraffin oil, and has been demonstrated also in frozen sections of lymphoid tissue from immunized animals by the fluorescent antibody technique. These observations have been taken to confirm the clonal selection theory of antibody formation (Chap. Thirteen), but they are consistent with, rather than confirmatory of, this theory.60

Antibody response in vivo. A general pattern in the relation of cells and tissues to the formation of antibody emerges from considerations such as the foregoing. The presence of antigen, or some fragment of antigen, within the antibody-forming cell

is presumably required to provide both stimulus and template. 12 Under experimental conditions demonstrable antigen may persist for extended periods, as, for example, the persistence of Vi antigen in the mouse for 231 days, an appreciable portion of the life span of this animal.29 It seems not to be necessary, as once thought, that such cells be phagocytic. Apparently the first step in the sequence of events known collectively as the immune response is phagocytosis of the antigen which is then transferred, possibly as a fragment, to lymphoid cells. Such transfer of antigen between macrophages and lymphoid cells has been observed to occur by cytoplasmic interaction,77 which apparently increases under antigenic stimulus. The presence of antigen in lymphocytes has been directly demonstrated by electron micrography and radioautographic methods.39 This initial step is that which is interfered with in blockade and similar procedures, and the preparatory stage accounts, in part at least, for the induction period elapsing between inoculation with antigen and the first appearance of antibody, and is a radiosensitive stage in the immune response. Some breakdown of the antigen molecule is possibly the basis of the apparent requirement that the antigen be me-

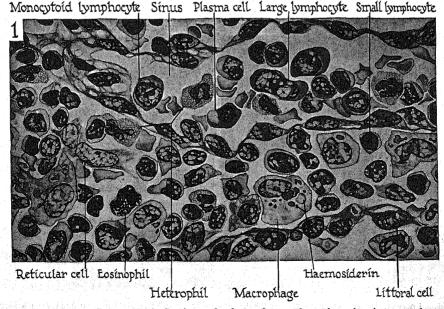

Figure 80. Cells of macrophage system. Sections of spleen of normal monkey showing a portion of a venous sinus and a Billroth cord in the red pulp; note the typical structure of the nongranular leucocytes, the reticular cells with indeterminate cytoplasm, and the rounded macrophages within the cord. \times 1240. (Taliaferro and Mulligan.)

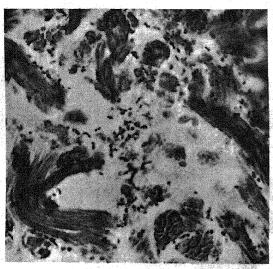

tabolized to some degree at least by the host tissues, and the rapid synthesis of antibody coincides with the disappearance of antigen in the blood.

The relative contribution of the antibodyforming mechanisms in various tissues to the total immune response is dependent upon the amount of antigen given and the route of its inoculation.78 When only small amounts of antigen are given other than intravenously, antibody tends to be formed locally, as in lymphoid tissue draining the area of inoculation, but large amounts of antigen given similarly spill out of the local area to stimulate antibody formation more generally. When the antigen is inoculated intravenously, the spleen is the site of early, and most intense, antibody formation, while antibody formation in other tissues tends to be somewhat less rapid but persists after the splenic response has declined.19 There has been some interest in mass immunization by inhalation of antigen, e.g., aerosol immunization, which tends to approximate in effect the intravenous route.21,30 While, then, the spleen is the most important source of antibody on appropriate initial antigenic stimulus, and as a consequence the antibody response is markedly affected by splenectomy, in the hyperimmunized animal the contribution of the spleen becomes less important, and antibody of nonsplenic origin becomes predominant.

The oral route, for many years somewhat discredited, has become the subject of renewed interest. It produces a superior coproantibody response as a consequence of local antibody formation in the lamina propria, but antigen by this route, other than infection produced by attentuated microorganisms as in live poliovirus vaccine, is inefficient as judged by serum antibody response.

Local immunity. The defense mechanisms functioning in the immune state have been assumed to be general ones and, for all practical purposes, equally effective throughout the body. It has been suggested, however, that these mechanisms are localized, or obviously accentuated, in certain tissues, not necessarily in tissues containing a large proportion of cells of the macrophage system, but tissues such as the skin, the intestinal mucosa, and the nasal mucosa.

Although attributable in some degree to the nature of the local defense factors, such as pH and the like, the predilection of an invading microorganism for some particular part of the body such as the central nervous system might be regarded as indicative of a relative susceptibility of certain tissues and, conversely, a relative resistance on the part of others—in Ehrlich's terminology, the presence or absence of cell receptors. In a disease such as typhoid fever or erysipelas, for example, it should be necessary then that only the intestinal mucosa or the

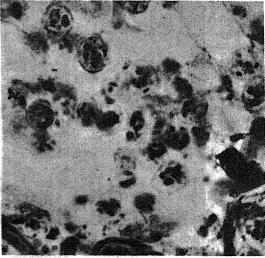

Figure 81. The cellular response in the immune animal. Rabbits injected subcutaneously with virulent pneumococci. Left, normal animal showing a typical spreading lesion with many extracellular pneumococci and minimal phagocytosis by polymorphonuclear leucocytes, Right, immune animal showing marked phagocytosis with intracellular agglutination and few extracellular bacteria. Sections stained by Gram's method; × 1050, (Cannon.)

skin be immune, the other tissues being already resistant. The evidence upon which it has been based is generally regarded as relatively weak, and local immunity in this sense probably does not exist.

Muco-antibody.68 There is. however. good reason to think that local immunity, not of a particular tissue such as the skin, no matter where it may be in the body, but of a local area, does exist, and is associated with local concentrations of antibody. Such antibody usually occurs admixed with mucus at mucous surfaces, and in this and other secretions is usually IgA. That present in respiratory mucus reflects the rise and fall of serum antibody titer, and is considered to represent extravasated serum antibody. In other areas, notably the bowel and the vagina, such antibody titer does not parallel serum antibody titer, but reaches a peak earlier and subsides while serum antibody continues to rise. Local formation of antibody, indicated by a superior local response and markedly inferior serum response following local application of antigen, is consistent with this discrepancy; *i.e.*, the later peak in serum titer is a consequence of the cumulative nature of serum titer, while the local titer is a reflection of the rate of antibody formation.

Such antibody is called muco-antibody because of its occurrence at mucous surfaces, and in the case of that found in the bowel, coproantibody. A variety of antibodies have been described as occurring locally, including those to dysentery bacilli and cholera vibrios, to poliovirus 51,53 and to the α -toxin of Cl. welchii in the bowel, to Trichomonas in the vagina, and to leptospira and poliovirus in the urine. 49,70

Natural Immunity

As pointed out elsewhere, the defenses of the normal animal against infection are of two general kinds. The first, characterized by nonspecificity with respect to the infectious agent, has been called resistance and has been discussed earlier. The second kind showing a greater or lesser degree of specificity, is considered here as natural immunity.

It is the rule rather than the exception that pathogenic microorganisms are sufficiently closely adapted parasites that they are able to establish infection only in more or less closely related species of hosts. Thus it is perhaps not to be expected that the same parasite will be able to infect organisms as widely different as higher plants and mammals. It is of particular interest, therefore, that *Pseudomonas aeruginosa*, a not uncommon pathogen of man and higher animals, has been found able to infect tobacco plants and may be identical with the plant pathogen *Phytomonas polycolor*.

While in Ehrlich's terminology it might be said that the cellular organization of the plant lacks receptors for the human pathogen, there is evidence of a positive type of resistance to such infection. Antibiotic substances, similar to those produced by bacteria and fungi, have been found in a number of higher plants. Thus, extracts of cabbage, turnip, onion, and barberry plants inhibit the growth of coliform bacilli and Bacillus subtilis; chlorophyll and related compounds have been found to inhibit the growth of the tubercle bacillus; and substances which inhibit the growth of Staphylococcus aureus and coliform bacilli have been found in a large number of angiosperms. None of the plants, however, is known to produce anything resembling antibodies.

Specific immunity. Natural immunity is often closely associated with the specific immune response, an immunity which is expressed in the form of the bactericidal and opsonic powers of normal blood, in the presence of the so-called normal agglutinins and the like. Such antibodies are generally present only in low titer, and the immunity associated with their presence in man is of a low grade but is possibly a significant part of that complex designated resistance. In many instances antibodies may be found under circumstances in which it is highly improbable that the animal has come in contact with the infectious agent; it has been noted, for example, that cattle serums will not infrequently neutralize the yellow fever virus and, more often, contain agglutinins

for bacteria such as the typhoid and dysentery bacilli, the cholera vibrio, and certain of the rare varieties of Salmonella. Although present in low titer, such normal agglutinins appear to be no different from the immune agglutinins in adsorbability, heat resistance, and the like, and such antibody activity occurs as all three classes, IgG, IgA, and IgM, of immunoglobulin. 15 The normal macrophage response does not involve this specific element, for all kinds of intact particles are phagocytosed. The question of the origin of these antibodies is, then, of some significance, and it may be asked whether or not specific antibodies may be formed in the absence of antigenic stimulation.

Natural antibodies.8 That the formation of some antibodies is genetically determined and takes place in the absence of antigenic stimulus is established in the case of the antibodies which determine the human blood groups. It is not unreasonable to suppose that in other instances the arrangement of polar forces on the surface of the normal globulin molecule might be such as to make possible to a greater or lesser extent the specific adsorption of antigenic substances. In fact, if the clonal selection theory of antibody formation (Chap. Thirteen) is valid, serum globulin would contain antibody, at least in trace amounts, to all possible antigenic specificities. The probability that this has any such practical reflection, if indeed it does occur, is not great, and it is unlikely that such an explanation is generally valid.

Inapparent infection. A second possibility that accounts for the presence of normal antibodies is that of inapparent infection. There is no reason to doubt that the average individual is exposed more or less continuously to a wide variety of microbial antigens, beginning post partum and extending throughout life. The microorganisms constantly present in the form of normal flora, especially of the respiratory and gastrointestinal tracts, provide a source of antigens seeping into the tissues. The protective activity of pooled normal adult gamma globulin against a wide variety of infectious agents⁵⁷ is no doubt an expression of such antibody content of normal human serum.

A case in point is that of the appearance of diphtheria antitoxin in the blood in the absence of clinically recognizable infection;

it is well known that the proportion of Schick-negative individuals increases in succeeding age groups. It is definitely established that the indicated formation of antitoxin is an immunity resulting from inapparent infection, i.e., the carrying of virulent diphtheria bacilli in the throat, and the antigenic stimulus of the presence of small amounts of diphtheria toxin. The agglutinins for Flexner dysentery bacilli and some of the common species of Salmonella associated with food poisoning, not infrequently present in normal human serums to titers of 1:80 to 1:160, in all probability are a consequence of subclinical infections. It is probable that such a sequence of events occurs in a number of diseases and that socalled normal antibodies, such as the neutralizing power of normal adult serum for poliomyelitis virus, measles virus, and other infectious agents, are, in fact, immune antibodies. The manner in which a pseudoracial immunity may be produced through infection has been discussed elsewhere.

Common antigens. As indicated above, however, there are many instances in which it is extremely unlikely that the animal whose serum agglutinates a given bacterium came in contact with it either as a mild infection or otherwise. It is difficult to conceive, for example, of the ordinary cow in the United States coming in contact with the cholera vibrio. In such cases it is not necessary to assume either that the observed antibodies arose de novo through some genetic or maturation mechanism or that there was contact with the particular microorganism. It is only necessary to assume that the animal has come in contact with an immunologically similar antigen. In this case the cholera vibrio is immunologically related to Brucella, and brucellosis, in cattle or in man, results in the appearance of cholera agglutinins in the serum.22 The likelihood that this will occur is clearly a function of the frequency with which immunological relationship or identity is shared by diverse organisms and the probability of contact with the unrelated form.

In addition to heterophile antigen, whose apparent random occurrence has been discussed elsewhere, immunologically similar antigens have been found to occur in a variety of seemingly unrelated organisms, and it is probable that many more have not as

vet been discovered. For example, crossreactions occur between type 2 pneumococcus polysaccharide and type B Friedländer's bacillus, certain species of yeasts, gum acacia and other vegetable gums, and some strains of coliform bacilli; the polysaccharide of type 14 pneumococcus is immunologically similar to the specific antigen of human blood group A; a constituent present in peptone is immunologically related to certain streptococcus antigens (group C); the capsule of the anthrax bacillus appears to be immunologically identical with that of B. mesentericus; the plague bacillus and paratyphoid B are immunologically related. From these examples it will be clear that immunologically similar antigens may be distributed in an apparently random fashion in unrelated organisms, and it is probable that in some, if not many, instances in which antibodies may be demonstrated for some microorganism with which infection or contact is unlikely, the antibodies are immune rather than "normal" and a consequence of exposure to a similar antigen.

In keeping with this discussion it may be pointed out that there is a strong possibility that there is no such thing as normal specific antibacterial immunity and that immunity in which a specific antibody may be demonstrated is one that arises as a consequence of exposure to the antigen. The incubation period following injection, for example, provides the opportunity for an immunological response that is difficult to rule out in many instances.

Acquired Immunity

Acquired immunity, as contrasted with natural immunity, is invariably an expression of a response to an antigenic substance. It is of two general kinds (in addition to the experimentally induced adoptive immunity described above), *viz.*, active immunity in which the immune individual forms his own antibody in response to an antigenic stimulus, and passive immunity in which the individual acquires preformed antibody produced by some other individual.

ACTIVE IMMUNITY

Active immunity is acquired as a consequence of exposure to the microbial antigen, either inadvertently as in infectious disease or inapparent infection as described above, or by deliberate inoculation with an appropriate antigenic preparation to give artificial immunization.⁶⁶ The last is, as pointed out by Edsall,²⁰ an attempt to get something for nothing. The objective is an effective immunity to disease, not a simple immune response in the technical sense, and it is in this connection that the immunogenic potency of antigens is assayed by the active protection test (Chap. Fourteen).

A number of immunizing preparations

and methods of producing an active acquired immunity may be used. These are:

- (1) The inoculation of living, fully virulent bacteria
 - (a) Rarely by a route favorable to infection
 - (b) Occasionally by a route unfavorable to infection
 - (c) In conjunction with protective antiserum
 - (d) Which are drug-dependent
- (2) The inoculation of attenuated bacteria of greatly reduced virulence for the host
- (3) The inoculation of bacteria killed by
 - (a) Heat
 - (b) Antiseptics
- (4) The inoculation of bacterial products
 - (a) Secreted during life
 - (b) Extracted from dead cells
- (5) The inoculation of bacteria unrelated to the production of the specific infection

These may be briefly illustrated.

(1) Immunity produced by the introduction of living, virulent microorganisms is practically identical with the immunity that results from an attack of disease after natural exposure. In experimental work the varying facility with which this mode of immunization can be effected is in part dependent upon the susceptibility of the organism to the particular parasite, and a highly susceptible animal can be immunized in this way only with great difficulty or not at all. The successful use of living cultures

involves the administration of small nonfatal doses which are increased as immunity develops.

The relative insusceptibility to infection by some particular route may be taken advantage of, as in Ferran's method, now superseded, for protective vaccination against Asiatic cholera; natural infection occurs via the alimentary tract and subcutaneous injection of the virulent vibrios is followed by a local inflammation but not by a general infection with serious consequences.

The simultaneous administration of virulent microorganisms and protective antiserum provides preformed antibody for combating the invader while allowing the immune reaction of the host to develop. This method is seldom used for the immunization of human beings but is common in some other instances; hogs may be immunized against hog cholera, for example, by simultaneous injection of virus-containing blood and antiserum. As has been described elsewhere (Chap. Seven), strains of pathogenic bacteria may be made drug-dependent in that they cannot grow except in the presence of the antimicrobial agent, and are virulent only when the host is treated with the drug. When such strains are inoculated into susceptible animals, they are unable to produce infection and disease.

(2) As indicated elsewhere, the virulence of pathogenic microorganisms may be greatly diminished in a variety of ways. such as cultivation under unfavorable environmental conditions and by passage through animal species other than that of the host in question.26 Perhaps the most familiar examples of the use of such attenuated material are those of smallpox vaccination and inoculation against rabies. In the first instance the virus of cowpox protects against smallpox infection, and in the second, rabies virus from dogs is "fixed." in Pasteur's terminology, or attenuated by serial passage in rabbits. This method is particularly useful in immunization against the virus diseases.

(3) Suspensions in physiological salt solution of bacteria killed by heating to 55° to 60° C. for 30 minutes or by treatment with formaldehyde or phenol are widely and successfully used in man against typhoid and paratyphoid fevers and against a variety

of microorganisms in the laboratory. Such vaccines are, in general, most useful in infections in which the microorganism does not produce a soluble toxin but contains an endotoxin. This method has the obvious advantage of avoiding all danger of infection while at the same time introducing into the body the substances most intimately connected with the bacterial cell and its activities.

(4) The use of products of the bacterial cell for immunization purposes finds widest application in the case of those organisms which produce soluble toxins. As pointed out above, a solid immunity against diphtheria may be secured by stimulating the production of antitoxin. It is possible to build up such an immunity by using extremely small amounts of unmodified toxin in the early injections with gradual increases as immunity develops. In general, however, it is much more satisfactory to use neutralized or detoxified toxin. In the first instance a neutral mixture of diphtheria toxin and antitoxin (TAT) is frequently used with satisfactory results; the complex breaks down slowly in the body, liberating free toxin which acts as the antigen. Toxoid prepared by treatment with formalin which has lost its toxicity but retains its antigenicity is generally used at the present time in a partially purified form precipitated by alum. The alum-precipitated toxoid is of some advantage since the toxin-alum complex breaks down slowly in the tissues, liberating toxoid slowly to provide a prolonged antigenic stimulus.

As pointed out earlier, antibodies to certain portions of the antigenic mosaic of the bacterial cell contribute more to effective immunity than antibodies to other portions. Untoward reactions resulting from inoculation with the intact cell may be due in part to antigens unimportant to the development of effective immunity, and if these are eliminated from the immunizing preparation, the amounts of essential antigen may be increased. Considerations such as these have led to chemical and immunological fractionation of plague bacilli, for example, in efforts to prepare more effective immunizing antigens.

(5) Some degree of immunity toward specific infections may be developed by the use of certain kinds of bacteria or bacterial

401

products entirely foreign to the infection in question. This protective effect seems to be of two general kinds. In the one, when the apparently unrelated microorganism contains antigens in common with the pathogenic form, the protection conferred is that of the conventional antibody response. The other is transitory and a manifestation of the protective effect of endotoxins of the gram-negative bacilli against some kinds of microorganisms. pathogenic This nomenon is well established and is, to a considerable degree, a consequence of a stimulation of the cellular defense mechanisms. 7, 44, 74

Irrespective of the antigen employed, the animal body requires time to respond with antibody production, and for a high degree of immunity successive antigenic stimuli are required. Early injections may consist of killed bacteria, followed by the inoculation of living, attenuated, or virulent cells. The process of forcing a very high degree of immunity upon an experimental animal is often termed hyperimmunization. The function of adjuvants in providing a persisting depot of antigen, and therefore a persisting antigenic stimulus to replace repeated inoculations, has been discussed earlier.

The immune response. The immunity produced is variable to some degree and dependent upon the efficacy of the antigen used. Some kinds of bacteria are good antigens, such as the typhoid bacillus, while others, such as the gonococcus, are poor antigens, and no effective immunity may be produced. The reason for this is not known. When an active immunity is produced, however, it is generally of long duration and effective over a period of years.

The immune response, as indicated by antibody titer, generally is apparent by the second of a series of injections, and the titer increases with succeeding injections until an upper limit is reached. With cessation of inoculations the antibody titer slowly declines and within a few weeks has reached a very low level. Subsequent injection brings about an immediate antibody response, much more rapid and pronounced than that of the initial immunization.

Ontogeny.^{34, 79} It has long been known that animals in the neonatal period are relatively poor antibody producers, and the phenomenon of immunological tolerance

SAUMA, BAALO LIBANA

(Chap. Thirteen) rests upon the basis that the highly immature cells of the fetus are unable to recognize the foreign nature of antigenic substances. Consistent with this, little or no γ -globulin is synthesized by the fetus, and in man and certain other mammals the γ -globulin, and antibody, content of fetal serum is of maternal origin (see below). In the neonatal human infant there is a steady decline in serum γ -globulin, to the extent that it may even reach a transient agammaglobulinemic level, but production is initiated in three to 12 weeks, although adult levels may not be reached for six, or even 10, months.

Failure to respond to antigenic stimulus with antibody production is attributable in large part to incomplete development of antibody-forming mechanisms, but there is evidence also that the presence of antibody of maternal origin has a depressive effect. However this may be, the potential antibody response of the fetus and the newborn has generally been underestimated, and, particularly in the latter, an antibody response may be elicited to strong antigenic stimulus, though it is usually inferior to that obtainable after further development. The antibody produced is almost entirely IgM.

The point in development at which a reasonable degree of immunological competence is reached, i.e., at which an antibody response is demonstrable, varies among species and with the kind of antigen. In the fetal lamb, for example, antibody to bacteriophage antigen is produced after 35 to 40 days of gestation, the homograft reaction is apparent at 85 days, but diphtheria antitoxin is not formed at six weeks after birth. Immunologic competence appears to develop much more rapidly in marsupials such as the opossum, in which antibody production is possible as early as 11 days after birth, but considerably later in pigs, cattle, guinea pigs, and rabbits. The human infant shows a detectable immune response to antigens such as diphtheria toxoid, poliovirus, and enteropathogenic coliforms at perhaps one month post partum, but the response is inferior to that obtained later. It is not possible to equate such antibody response entirely in terms of potential immunological competence, for contact with antigen appears to stimulate development of the antibody-forming mechanisms.

STEEN BUT

Lymphocytopoiesis. Immunological sponsiveness appears to parallel closely lymphocytopoiesis,* and the role of the thymus in mammals has been of particular interest.⁵⁶ In man, and many other animals, the thymus appears to be essentially the sole source of antenatal lymphocytes which arise by transformation of epithelial cells, beginning at about two months in man, and at varying times in other species. Thymic lymphocytes migrate peripherally to establish centers for the development of lymphoid structures and, with advancing age, contribute in large part to the lymphocyte population. Proliferation of lymphocytes in lymphoid structures, such as the spleen and lymph nodes, is normally limited, but is markedly accentuated by antigenic stimulus. In the extreme case of germ-free animals, the lymph nodes are atrophic, with little or no evidence of mitosis, while the thymus is fully developed and actively lymphocytopoietic. On antigenic stimulation germinal centers appear in the spleen, lymph nodes, and other lymphoid tissues, showing mitotic activity and active lymphocytopoiesis coincident with the production of antibody. Such peripheral centers, then, appear to constitute the morphologic facet of the antibody-forming mechanism, although the thymus continues to manufacture lymphocytes at a steady rate.

Thus in the mouse, thymectomy within 24 hours of birth initiates a wasting syndrome characterized by loss of weight, cachexia, etc., which is fatal in perhaps a month. Such animals are immunologically unresponsive, and the terminal lymphocytopenia is marked. When the removal of the thymus is delayed, this syndrome is not produced and the animals are immunologically responsive. The persisting significance of continued lymphocytopoiesis in the thymus is indicated by failure of animals subjected to delayed thymectomy to recover from radiation damage; i.e., following radiation destruction of peripheral lymphoid tissue, regeneration would appear to be dependent upon thymic lymphocytes. There is evidence also that the role of the thymus. at least in mice, may also include a humoral factor affecting lymphocytopoiesis. 47

While the thymus plays a primary part in

lymphocytopoiesis and the development of the antibody-forming mechanisms in many animals, in certain species other lymphoid tissue may take over this function in whole or in part. It is firmly established that the bursa of Fabricus in the chicken is a highly significant element in immunological responsiveness, ⁹⁷ so much so that it has been referred to as a "cloacal thymus." There is evidence too that the appendix in the rabbit functions similarly.⁸⁵

Polyvalent and multiple antigens. high specificity of the immune response may require more than one strain or kind of microorganism to give effective immunity to a disease entity. Influenza, for example, is caused by a number of antigenically distinct strains of the virus with little or no cross-protection among them, and an immunizing preparation producing an immunity to the disease must include the relevant strains. Similarly, cholera vaccine often contains the two major serotypes of the vibrio, and typhoid vaccine may be combined with the paratyphoid A and paratyphoid B bacillus vaccines. Such immunizing preparations are known as polyvalent vaccines. The use of polyvalent vaccines is limited in practice by the number of components which are required. The total amount of antigenic material that may be administered without unduly severe reactions is limited. When, then, many components are required, the amount of each consistent with a tolerable reaction to the preparation may be so limited that no individual component is sufficient to provoke an effective immune response.

For the purely practical purpose of limiting the number of parenteral inoculations, it may be desirable to combine widely different immunizing agents as a multiple antigen. Commonly used combinations are, for example, pertussis vaccine and tetanus and diphtheria toxoids in some combination. The use of multiple antigens, and polyvalent vaccines, raises the question of whether or not the independent immune response to each of the antigenic components is adversely affected by the presence of the others, i.e., whether the individual antibody responses are suppressed when they occur simultaneously. In some combinations there is some suppression of the immune response, but in others there may be an accentuation. The latter effect appears

^{*}The term lymphocyte is used loosely here to cover the range of cells, including plasma cells, of the lymphoid series.

often to be due to an irritant effect of one antigenic preparation that accentuates the response to an accompanying relatively bland antigen. Various combinations of antigens behave differently, and the immunizing efficiency of multiple antigens cannot be generalized. 10, 35, 67

Precocious protection. 10, 35, 67 It has been observed from time to time that within a few hours after inoculation with an immunizing antigen, the recipient develops an appreciable resistance to challenge inoculation which is usually, but not invariably, specific. For example, such a transient resistance develops rapidly after inoculation with typhoid or pertussis vaccine, in the latter instance reaching a peak in eight to 10 days and prior to the appearance of demonstrable antibody. The phenomenon has also been observed with tetanus and diphtheria toxoids and with typhus fever rickettsiae.

This transitory protective effect is distinct from the active immune response and is usually regarded as an interference effect, based upon competition between the inactivated immunizing antigen and the challenge inoculum for tissue receptors. As such, it is closely similar to, if not identical with, the interference phenomenon among viruses (Chap. Four).

PASSIVE IMMUNITY

In contrast to active immunity, passive immunity involves no active generation of protective substances by the immunized animal. The latter is simply the recipient of antibodies formed in the body of another animal and transferred to the individual to be protected.³⁴ Such passive transfer occurs in nature from mother to offspring, *in utero* via the placental circulation in man, apes, and rodents, in which there are only two layers of cells between the maternal and fetal circulatory systems, and after birth via the colostrum in ruminants, in which there are four layers of cells between the two circulatory systems.

The nature of the transfer of maternal antibody to the fetal circulation is not altogether clear. It is probable that the placenta does not play a significant part in antibody formation, and presumably it is a process of diffusion from the maternal

circulation. It has been observed that antibodies to different antigens are transferred to varying degrees; viz., that to mumps and Japanese B encephalitis is relatively complete, while antibody to vaccina and poliovirus shows considerable disparity between maternal and fetal titers.⁵⁰ Of the antibody classes, only IgG appears to be transferred in utero.

Absorption of antibody present in colostrum and milk occurs readily, at least in the immature animal, 9, 37, 38 and makes possible passive immunization of the newborn when transfer of antibody from the maternal circulation is not effective. Local formation of antibody occurs in the lactating mammary gland, and it appears to respond exceedingly rapidly to local antigenic stimulus. There is some evidence suggesting that local antigenic stimulus may be provided by microorganisms present in the suckling young, with consequent rapid return of antibody to the infant whose antibody-forming capacity is as yet poorly developed.

Artificial passive immunization is brought about by the injection of immune serums such as the antitoxic serums of horses immunized against diphtheria toxin, tetanus toxin, and similar antigens, or of convalescent serums taken from humans who have recovered from the disease in question. As noted above, the γ -globulin separated from pooled adult plasma contains antibodies to the infectious agents encountered early in life, and is used for passive immunization of the young against infections such as measles. Passive immunization is most effective with antitoxic serums; with exceptions such as virus-neutralizing serums, antipneumococcus serums and the like. antibacterial serums are generally not highly effective either prophylactically or therapeutically.

Unlike active immunity, passive immunity is not of long duration, generally not more than two or three weeks. Repeated injections of tetanus antitoxin, for example, must be made at weekly intervals as long as the danger of infection remains. Horse serum globulin acts as a foreign protein in the human body and tends to be eliminated as such. Passive immunization with homologous serum is possibly of somewhat longer duration; diphtheria antitoxin passively transferred in utero has been found to have a half-life of four and one-half weeks.

Hypersensitivity

The response of the animal body to the presence of antigen in the tissues is clearly an advantage when the antigen is a toxin or the cell substance of a pathogenic microorganism. It was early apparent, however, that initial inoculation of an antigen may so sensitize the animal that subsequent inoculation results in the development of a typical symptom complex and perhaps death, and in such cases the animal is said to be hypersensitive.4 This effect is apart from such phenomena as the neutralization of toxin by antitoxin and is most striking when the antigen is initially bland. While it may play some part in effective immunity, there is also reason to believe that hypersensitivity to the cell substance of bacteria may, in some instances, contribute to the pathology of the disease resulting from infection as, for instance, in acute rheumatism and arthritis, and hypersensitivity to nonliving antigens may also result in disease of noninfectious nature. Hypersensitivity is quite general and may take a variety of forms in both experimental animals and man. It may be divided here into three general categories:

(1) Anaphylaxis and related hypersensitivities

(2) Allergy and/or atopy

(3) Infection hypersensitivities

Of these, the first two are of the so-called immediate type in that reaction to the antigen occurs within a few minutes or hours, and the hypersensitivity is usually passively transferable by serum. They are distinguished from one another most obviously by the generally artificial nature of anaphylaxis, in a sense a laboratory phenomenon though it may occur under natural conditions, and by the spontaneous sensitization to environmental agents characterizing allergy and atopy. Infection hypersensitivities are somewhat set apart by their being delayed reactions, i.e., reaction to the antigen is delayed one to four days, and by their failure to be passively transferred by serum.

ANAPHYLAXIS18

The state of the s

The sensitizing effect of an initial inoculation of antigen was observed by Richet in 1902 in a study of the immunization of

dogs with toxic extracts of the sea anemone. About this same time Theobald Smith noted the lethal effects of second and third inoculations of diphtheria toxin-antitoxin in the guinea pig when the inoculations were widely spaced, and in 1905 Otto found that the active agent in the mixture was horse serum. This was subsequently studied in considerable detail by Rosenau and Anderson, and the general picture is now quite clear.

Anaphylactic shock. If a guinea pig is inoculated with horse serum at intervals of perhaps four to eight days, it responds with the development of an immunity, and precipitating antibody appears in the serum. If, however, an interval of 10 to 12 days elapses between the first and second inoculations, the animal becomes hypersensitive as a consequence of the first inoculation. and the second is highly toxic. The state of hypersensitivity so induced by the sensitizing dose is designated anaphylaxis, and the reaction produced by the second, or shocking dose, is anaphylactic shock. This phenomenon of anaphylaxis is a laboratory artifact in that it results from the purposeful inoculation of antigen into the tissues, and shock is produced by the rapid inoculation of relatively large amounts of antigen, usually directly into the blood stream. It is artificial in that it occurs only under conditions set up by man, in experimental inoculation of animals and in serum therapy in

The sensitizing dose may be exceedingly small, as little as 0.000001 ml. of horse serum in the guinea pig, and varies with different antigens and different experimental animals. The shocking dose is considerably larger, 0.1 to 0.01 ml. of horse serum for the guinea pig. Quantitative studies with a pure antigen, crystalline ovalbumin, have indicated that somewhat larger doses may be required. Guinea pigs sensitized with 10 μ g. of ovalbumin could sometimes be fatally shocked with as little as $0.5 \mu g$., and doses of 1 µg, gave fatal shock in about 40 per cent of the animals. Within a certain range the severity of the shock produced is directly related to the size of the shocking dose; i.e., mild shock is produced by a small dose and lethal shock by a larger dose. The route of inoculation of the sensitizing dose is not

important. For some animals and some antigens several sensitizing doses may be required to develop hypersensitivity, but in any case the doses must be small and widely spaced. A single dose suffices to shock, and the route of inoculation is important. Intravenous and intracardial inoculation is most effective, and, in the guinea pig, which is the most readily sensitized and shocked of the usual experimental animals, intraperitoneal inoculation of the shocking dose is effective, but the reaction is delayed and larger doses are required.

Once established, the anaphylactic state persists more or less indefinitely but diminishes appreciably in the guinea pig after a few weeks. If the shock produced is not lethal, the animal is temporarily refractory, that is to say, is desensitized, but hypersensitivity reappears, in the case of the guinea pig after perhaps two weeks or less. Guinea pigs, rabbits, and dogs are the common experimental animals, but birds may be sensitized, while mice, rats, and monkeys can be sensitized only with difficulty and then irregularly. The symptoms and postmortem pathology are essentially identical within a given animal species regardless of the antigen used, but differ from one animal species to another.

The guinea pig. Following inoculation of the shocking dose the animal remains quiet for a few moments but very soon becomes restless, the fur becomes ruffled, and the animal rubs its nose and sneezes. Clonic and tonic convulsions set in, the animal falls to its side, respiration becomes labored, and the animal dies gasping for breath while the heart continues to beat. This symptom complex is produced in varying degree in nonfatal shock. The outstanding postmortem findings are the marked distention of the lungs and hemorrhages on the underside of the diaphragm. The lungs remain distended after the thoracic cavity is opened and when removed from the body and cut. The bronchioles are sharply constricted with the retention of air in the alveoli, and the immediate cause of death is suffocation. The contraction of the bronchioles is not prevented by vagotomy or curare and is muscular or immediately neuromuscular in origin.

The rabbit. The rabbit is less susceptible to anaphylactic shock than the guinea pig, and, in contrast, develops shock only

after a series of immunizing inoculations and after circulating antibody is demonstrable. Shock may be delayed and occur several hours after administration of the shocking dose. The symptoms and pathology differ sharply from those in the guinea pig, with absence of difficulty in respiration. The animal falls on its side, shows convulsive movements, and passage of feces and urine. Respiratory movements may continue briefly after the heart has ceased to beat. On autopsy the pulmonary dilatation found in the guinea pig is absent, and the most conspicuous and characteristic feature is the extreme dilatation of the right side of the heart. The immediate cause of death is heart failure resulting from constriction of the branches of the pulmonary artery and consequent dilatation.

The dog. Anaphylactic shock in the dog occurs in two stages. The first is characacterized by restlessness; the animal vomits and passes urine and feces and collapses with signs of extreme muscular weakness, and respiration is labored. The blood pressure falls rapidly as a consequence of capillary dilatation and stasis in the tissues. In nonfatal shock recovery from this stage is rapid, but in fatal shock the weakness is progressive, vomiting and diarrhea continue, convulsions may occur, and the animal becomes comatose and dies. On autopsy the outstanding feature is the congestion of the viscera and the pronounced distention and congestion of the liver, which is a consequence of constriction of the hepatic veins and injury to the liver cells resulting in edema from the transudation of fluid.

In addition to the characteristic phenomena noted above, anaphylactic shock also has common features which may be more or less pronounced in different animal species. Fall in body temperature is usual and leucopenia occurs which results from aggregation of leucocytes in the capillaries. Coagulation time of the blood is increased, usually most marked in the dog, as a result of the liberation of heparin rather than direct interference with the clotting mechanism, and serum complement is reduced. Congestion and hemorrhage of the gastrointestinal tract are common postmortem features.

Passive anaphylaxis. Anaphylactic hypersensitivity is passively transferable from sensitized female guinea pig to offspring and

by inoculation with serum from either sensitized or immunized animals. It can be produced with a high degree of consistency by inoculation of guinea pigs with immune rabbit serum and is a function of the amount of antibody, both precipitating and nonprecipitating, in the serum. As little as 0.03 mg. of rabbit or guinea pig antiovalbumin nitrogen suffices to passively sensitize guinea pigs, and univalent antibody is equally effective. The recipient is not immediately sensitized following the injection of antiserum and usually, though not invariably, a period of some hours elapses before sensitivity appears. If antigen is injected first, followed by the inoculation of antiserum, reversed passive anaphylaxis occurs, also usually some hours after inoculation of serum.

Function of haptenes in anaphylaxis. The specificity of the anaphylactic reaction may be, and probably frequently is, determined by haptenes. In general, sensitization can be accomplished only by complete antigen, but in a few instances simple compounds, including arsphenamine, picryl chloride, and 2.4-dinitrochlorobenzene, have been shown to sensitize guinea pigs, and sensitization to arsphenamine has been observed in man. Haptenes will usually not elicit shock, though some of the larger molecules such as azo dves will do so, but the inoculation of haptene specifically prevents shock by inoculation of the complete antigen. The role of haptenes in specificity is further shown by the use of conjugated antigens containing the same haptene but different proteins; thus, guinea pigs sensitized with a conjugated globulin can be shocked with the corresponding conjugated albumin.

Anaphylactic shock in isolated tissue.¹ It will be clear from the foregoing discussion that the occurrence common to anaphylactic shock in different animals is a contraction of the smooth muscle, predominantly in the bronchioles in the guinea pig, in the pulmonary artery in the rabbit, and in the hepatic veins in the dog, and in all three the gastrointestinal tract is affected. It is, then, of considerable interest that anaphylactic shock, manifested as a sharp and abrupt contraction, can occur in isolated smooth muscle. This was observed by Schultz in 1910, using portions of intestine, and studied in detail by Dale with uterine

horn, and is now generally known as the Schultz-Dale technique. The uterine strip is suspended in a bath of Ringer's solution with one end tied fast and the other attached to a kymograph, and the contractions are recorded when antigen is added to the bath. The reaction is exquisitely sensitive, a sensitized strip giving typical contraction in final dilutions of horse serum antigen as high as 1:1000 million, and sharply specific. All the essential features of anaphylaxis may be reproduced in vitro by this method, including active or passive sensitization of the uterine strip in vivo, passive sensitization in vitro, specific desensitization, etc. It is significant too that uterine horn from immunized as well as sensitized guinea pigs will respond to antigen with shock.

Mechanism of anaphylactic shock. It will be clear that anaphylaxis rests on an immunological basis and that shock is the result of antigen-antibody reaction. There is good reason to believe that the union is one of antigen with intracellular or sessile antibody. For instance, as just indicated, sensitization and shock may be produced in isolated tissue, and the incubation period in passive sensitization is regarded as necessary for the taking up of inoculated antibody by the cells. Desensitization consists of saturating, or nearly saturating, sessile antibody, and the protective effect of immunity is a prevention of antigen reaching intracellular antibody by union with serum antibody. Antigen-antibody complexes have pharmacological activity, and soluble complexes prepared with excess antigen will produce various manifestations of hypersensitivity, including anaphylactic reactions, skin reactions (see below), etc., in the normal intact animal or isolated tissue. 69, 98, 99

The manifestations of anaphylactic shock are closely similar to those produced by histamine and substances having histamine-like activity. In the guinea pig, for example, constriction of the bronchioles is produced which is indistinguishable from that of acute anaphylactic shock, and histamine and similar substances produce contraction of isolated smooth muscle in the Schultz-Dale reaction. It is generally believed that the antigen-antibody complex formed affects the cells and tissues in a way, as yet unknown, that results in the release of histamine-like substances. There is no reason to believe that antibody is fixed primarily or even pre-

dominantly in smooth muscle cells, but there is a high correlation between histamine sensitivity and the cells concerned in anaphylactic shock. Furthermore, the tissues affected in anaphylactic shock are those that show the highest content of histamine; there is some evidence which suggests that leucocytes are a source of histamine and, as indicated above, they aggregate in affected tissues in shock. In addition many, though not all, substances showing antihistamine activity appreciably or markedly modify anaphylactic shock; of these epinephrine and ephedrine are among the most effective.

While the activity of histamine and its resemblance to anaphylactic shock, and other manifestations of hypersensitivity, have been known for a long time, it is probable that other substances are concerned also. For example, antihistamines are only partially effective in inhibiting anaphylactic shock: the increased clotting time characteristic of anaphylaxis is not produced by histamine: refractoriness to histamine is not necessarily associated with refractoriness to anaphylactic shock, etc. Of other histamine-like substances, serotonin (5hydroxytryptamine) has also been associated with anaphylactic reactions. For example, both histamine and serotonin are released when antigen and antibody are added to a plasma suspension of normal rabbit platelets⁴⁶ and occur in rabbit blood during anaphylactic shock. The possibility that the predominant substance may differ from one animal species to another is suggested by the high content of histamine in the guinea pig lung, which contains little serotonin, and the reverse relationship in the mouse lung, 100 and the partial protection of guinea pigs but not mice by some antihistamines, while lysergic acid diethylamide, a serotonin inhibitor, protects mice.25 That more than one histamine-like substance may be effective in a single animal species is suggested not only by the incomplete protection given by antihistamines, but also by the observation that smooth muscle from an animal sensitized with multiple antigens reacts to each antigen successively; i.e., the contractile stimulant is not exhausted in one reaction.

A possible neurogenic mechanism in hypersensitivity reactions has been of interest in connection with the role of nerve conduction in the Schultz-Dale reaction. For example, stimulation by antigen or serotonin, but not by acetylcholine or histamine, is

inhibited by structural analogues of serotonin such as gramine, yohimbine, and bufotenine, suggesting that the antigen-antibody reaction may liberate serotonin. Treatment of the muscle preparation with botulinum toxin (Chap. Nine), however, blocks stimulation by antigen but not by serotonin, which has been taken to indicate that the toxin blocks the release of serotonin.

The nature of the pharmacological reactions mediated by the antigen-antibody union is clearly a highly complex one.

The Arthus phenomenon. The Arthus phenomenon is a local hypersensitivity reaction produced in actively and passively sensitized animals, which is closely related to, but not identical with, anaphylaxis, and which has been called a form of local anaphylaxis. If rabbits, for example, are injected repeatedly with antigen such as horse serum, a local reaction appears which becomes more and more intense as the inoculations are repeated. The site of inoculation first shows a transient swelling, but later the swelling and edema persist and progress to induration and local necrosis. This local phenomenon is a result of a general sensitization, since later inoculations need not be in the same site as earlier ones. The Arthus phenomenon appears to be confined to the rabbit among experimental animals, or at least is very difficult to produce in other animals, but occurs with some frequency in man, as during protracted series of inoculations with antiserum or an antigen such as rabies vaccine.

The rapidity of the reaction and its intensity are correlated with the amount of precipitable circulating antibody as well as with the amount of antigen inoculated. The reaction is an immediate one in that a cellular response is demonstrable histologically within an hour, but it does not become grossly apparent for several hours. The local antigenantibody reaction results in the deposition of the complex in the tissue adjacent to the site of inoculation, with preferential location in and on either side of the basement membranes of the small blood vessels.75 Such localization undoubtedly contributes to the vascular necrosis which is a prominent feature of the histopathology of the lesion. When a dye is inoculated with the antigen, it diffuses rapidly in the skin of a normal animal but is localized when the animal is sensitized; this reaction is referred to as passive cutaneous anaphylaxis (PCA) when used for the detection of skin-sensitizing antibody. 65 The Arthus reaction may also be reversed by the administration of antigen, followed several hours later by the local inoculation of antibody.

Serum sickness. The inoculation of man with antiserum, usually from the horse, produces in some persons a characteristic syndrome termed serum sickness. The symptoms include rash, often urticarial in nature, fever, joint pains, some edema, and swelling of the lymph glands regional to the site of inoculation, in combinations and emphasis that are variable from one individual to another. This reaction is to be distinguished from the febrile and local reactions commonly following the inoculation of foreign protein and is most often attributable to a hypersensitivity to horse serum irrespective of its antibody content, though essentially similar reactions may be produced following the inoculation of toxoids, vaccines, etc., as a consequence of hypersensitivity to constituent antigen. The incubation period may be as short as two hours or as long as 24 days, and most often is eight to 12 days. The reaction may follow initial inoculation of horse serum, but more frequently there is a history of prior inoculation. It is specifically antagonized by epinephrine, ephedrine, etc., and, like anaphylactic shock, is presumably a consequence of the sudden liberation of histamine in toxic amounts.

The hypersensitive individual gives an immediate reaction, *i.e.*, within 10 to 20 minutes, to the intradermal inoculation of 0.1 ml. of 1:10 dilution of horse serum or the instillation of a drop of horse serum in the conjunctival sac. In the first instance an irregular wheal surrounded by an erythematous zone constitutes a positive reaction, and in the second diffuse conjunctivitis appears in the hypersensitive individual.

Under certain circumstances, such as the prophylaxis of tetanus with antitoxin, desensitization may be carried out relatively rapidly. The usual procedures, after a preliminary test for sensitivity by intradermal inoculation of 0.02 ml. of a 1:10 or 1:100 dilution of the serum, include the administration of drugs such as diphenylhydramine hydrochloride, epinephrine, and corticotropin by intravenous drip, and, after 30 minutes or so, small amounts, 0.1 ml. of a 1:100 dilution, of antiserum are given subcutaneously. Successive inoculations can be given at relatively short intervals, 10 to 15

minutes, and doubled with each inoculation. Eventually 1 ml. doses can be given every 15 minutes until the total dose of antitoxin has been administered.⁸⁸

The question may be raised as to why serum sickness rather than anaphylactic shock occurs in the hypersensitive individual. In general there seems to be little tendency in man to generalized shock in this and other manifestations of hypersensitivity, and, as in dogs and monkeys, there is a tendency to localization of the manifestations of the reaction to the respiratory tract, the gastrointestinal tract, and the skin. A number of instances of typical anaphylactic shock have been reported in man though it is rare, and when generalized shock occurs it is often fatal.

ALLERGY AND ATOPY

Serum sickness is perhaps best regarded as a form of anaphylaxis in man, but only a small part of the manifestations of hypersensitivity are those of serum sickness; the remainder may be grouped under the general head of allergy. Like anaphylactic shock, an allergic reaction is a consequence of the union of antigen with sessile antibody. The antigen is often designated allergen and the corresponding antibody reagin because it was thought earlier that they differed from antigen and antibody. It is now generally recognized that there are no essential differences, but the terms persist even though a number of workers have urged that they be dropped.

There are a number of differences between anaphylaxis and allergy which are rather of degree than of kind, but which in the aggregate tend to distinguish them. Thus, allergy is naturally acquired while anaphylaxis is artificially produced; allergy is often a hypersensitivity to nonprotein antigens while anaphylaxis is only rarely so; allergic hypersensitivity is of long duration while that of anaphylaxis is limited; desensitization is usually difficult and incomplete in allergy and effective in anaphylaxis; and edema is a prominent feature of the allergic reaction and smooth muscle contraction a minor factor while the reverse is true in anaphylaxis.

Some workers divide the clinical allergies into two general groups: atopy (strange disease) or atopic allergy, and nonatopic al-

ALLERGY 409

lergy. The atopic allergies include the pollen and dander sensitivities resulting in hav fever and asthma and some of the food and drug allergies. Contact dermatitis and the remainder of the food and drug allergies make up the nonatopic group. The distinction between the two is quantitative rather than qualitative, and it is doubtful whether it is of any real validity, but it does have a certain clinical utility. It was first made on the basis of heredity, hereditary predisposition being an important factor in atopy, and it has even been postulated that in atopy initial contact with the antigen is not necessary for the development of the allergic state. On the other hand, in the nonatopic allergies there is almost always a history of contact with the antigen, such as continued exposure to nitrocellulose products in industry, and the hereditary predisposition seems to be of minor importance. There are other correlated characteristics. In atopic allergy the sensitivity is very high, desensitization is difficult and usually only partial at best, skin reactions are marked and specific, and considerable amounts of antibody are demonstrable in the serum. In nonatopic allergy the converse generally holds: i.e., sensitivity is low, desensitization is usually successful, skin reactions are weak and nonspecific, and little antibody is demonstrable in the serum. These distinctions are, however, purely relative.

Heredity. It has been a matter of some interest that inheritance of a predisposition to at least some forms of allergy is an important, perhaps often a determining, factor. The constitutional factor is a predisposition only, and contact with the antigen is essential to the development of the allergic state. Inheritance in man is frequently difficult to demonstrate, but detailed studies on familial association have made it highly probable that predisposition to allergic hypersensitivity is genetically determined. It has been suggested that the predisposition is determined by a pair of allelomorphic genes, H determining nonallergy and h allergy. The possible genotypes are HH or pure normal, hh determining allergy which develops before puberty, and Hh the normal transmitter in which allergy may develop after puberty. In confirmation of observations on man, the inheritance of predisposition to sensitization has also been shown in experimental animals. The significance of heredity in allergy has been said to distinguish this form of hypersensitivity from anaphylaxis, but it is not clear that this is a basis of distinction.

Forms of allergy. The allergic state is manifested in a variety of forms which are determined by two interrelated factors, the portal of entry of the antigen and the tissue predominantly affected, usually referred to as the *shock organ*. Thus the antigen may be inhaled, ingested, injected, or may simply make contact with the skin. The tissues affected are those of the upper respiratory tract, the gastrointestinal tract, and the skin. These combinations give rise to a number of commonly occurring, well-defined clinical types, *viz.*:

Hay fever. This is a seasonal allergy produced by the inhalation of pollens from trees, grasses, and weeds, and time of occurrence is determined by time of pollination, i.e., trees and grasses from late spring to midsummer and weeds in late summer and early fall. In the United States ragweed pollen is one of the most common offenders. Nonseasonal hay fever is a result of hypersensitivity to animal danders, orris root (a constituent of many cosmetics), and house dust. The mucous membranes of the upper respiratory tract are affected primarily.

Asthma. Essentially the same inhaled antigens are responsible for asthma as for hay fever, and in addition book bindings, straw, and similar materials are sometimes involved. The individual may become sensitive to bacteria of the normal flora of the upper respiratory tract, giving rise to so-called endogenous asthma. The shock organ is the lining and musculature of the bronchi in bronchial asthma, by far the most common type, and swelling of the mucosal lining and spasm of the muscles results in obstruction of the smaller bronchioles and consequent difficulty in breathing. Allergic asthma may also result from the ingestion of foods, such as eggs, milk, wheat, or various drugs. It may be noted that asthma is a symptom complex and not always allergic in etiology.

Dermatitis. Dermatitis of allergic etiology may result from contact with the antigenic substance or from ingestion or inhalation of antigen. The former is frequently referred to as contact dermatitis and is often an occupational disease resulting from repeated contact with substances such as lacquers, nitrocelluloses, glue, and the like. Ingested antigen not infrequently affects the skin as the shock organ, giving rise to a noninfectious eczema in infants and what is often called neurodermatitis in the adult.

Urticaria and angioneurotic edema. When the skin is the primary shock organ an inflammatory reaction accompanied by some degree of edema results. Urticaria, or hives, is the occurrence of whitish or pink elevations which come and go repeatedly within short periods, and is the most common lesion. In angioneurotic edema, or giant urticaria, edema is much more pronounced, and the lesions are large pale swellings which cover areas such as the eyelids, lips, and genitals. Hives and this edematous kind of lesion are frequently found together and most often result from hypersensitivity to ingested or injected antigen, i.e., foods and drugs.

The foregoing clinical types are characterized by the symptom complex produced, but types of allergy may also be differentiated on the basis of kind and portal of entry of antigen, viz.:

Drug idiosyncrasy. As indicated above, an allergic antigen may be a simple chemical compound, and when this is a drug the condition is a drug allergy or drug idiosyncrasy. The allergic sensitivity is to be differentiated from the sensitivity of a low tolerance for the drug; in the first instance the symptoms are those of the allergic reaction, while in the second they are produced by the pharmacological action of the drug. The drugs commonly involved are the barbiturate derivatives, salicylic acid compounds, phenolphthalein, opiates, sulfonamides, occasionally the antibiotics, the arsenicals, and others. These are either ingested or injected. The most common reactions are urticaria and dermatitis; bronchial asthma is less frequent.

Food allergy. The ingested antigens include food as well as drugs, and strawberries, milk, and eggs are the most common offenders. The shock organ in food allergy is usually the skin, and the most frequent lesion dermatitis or urticaria, and, less often, bronchial asthma. In addition, the gastrointestinal tract is often affected

directly with resulting disturbance.

Pollen and dander allergies. These antigens are inhaled, and the symptoms are almost always those of involvement of the upper respiratory tract, most commonly hay fever, and bronchial asthma somewhat less so.

Contact allergies. This is almost entirely the contact dermatitis noted above and is not only an occupational disease, but not infrequently results from cosmetics, the lacquers such as nail and hair lacquers, and powders containing orris root.

It will be clear from the foregoing that it is difficult if not impossible to generalize to a satisfactory degree the various interrelated forms of allergy, and the source of the difficulty is that they are not fundamentally different.

Allergic antigen and antibody. As indicated above, the allergic antigens or allergens (sometimes called atopens in the atopic allergies) are frequently nonprotein in nature. This is most obvious in the case of the drug idiosyncrasies in which synthetic substances, such as barbiturates, antipyrine, and the like, are clearly not contaminated with protein. Similarly, the substances responsible for contact dermatitis, such as lacquers, are protein-free. The more complex, naturally occurring allergens such as pollens, danders, and foods are, of course, not protein-free, but the active agent in some pollens is of lower molecular weight, perhaps 5000, than the usual antigenic proteins. There is no doubt that haptenic substances can produce the allergic reaction in a sensitized individual,

at least in experimental anaphylactic shock, but the question of sensitization is more difficult. High molecular weight nonproteins can act as complete antigens; for example, sensitization may be induced by pneumococcal polysaccharide. It is probable, however, that the relatively simple substances, such as the arsenicals, do not function as sensitizing antigens in themselves, and it is generally believed that they combine with body protein to give a conjugated complete antigen whose specificity is determined by the haptene, which functions as the sensitizing antigen. It is not clear, however, whether the shocking antigen is such a conjugated one or whether the haptene alone usually produces shock.

It may be noted here that allergic hypersensitivity to physical stimuli, heat, cold, and light, may occur. It is unlikely that such stimuli alter body proteins so that they become iso-antigens, and such allergies probably do not have an immunological basis.

On intradermal inoculation of soluble antigen, or its application as a patch on the intact skin, the sensitized individual gives a skin reaction characterized by local erythema and the appearance of a wheal. The skin reaction is more readily elicited and more specific in some allergies than in others. In general it is not satisfactory in contact dermatitis and some of the food and drug allergies. This kind of skin test is to be distinguished from tests like the Schick and Dick tests, in which the reaction is produced by diptheria or scarlatinal toxin and neutralized by circulating antitoxin, which have no relation to hypersensitivity.

Antibody⁸¹ is demonstrable in many of the allergies, particularly those grouped under the head of atopy. Its presence may be shown directly in some instances by complement fixation, but the usual measure is passive transfer of the sensitivity. If a small amount, 0.1 ml., of serum from a sensitized person is inoculated intradermally into a nonsensitive person and the antigen inoculated intradermally in the same area 24 hours later, a positive reaction occurs. The local sensitization may persist for four weeks or more. Such passive transfer cannot be made to guinea pigs but has been made to rhesus monkeys, and it is probable that a close phylogenetic relationship is essential. This passive transfer was described by Prausnitz and Küstner in 1921 and is known as

the Prausnitz-Küstner reaction. A reversed passive sensitization, analogous to reversed passive anaphylaxis, may be produced by inoculation of antigen first, and serum 24 hours later. In the usual terminology, the antibody which produces passive sensitization is the allergic reagin, and it appears to be exclusively IgA.

As in the case of anaphylactic shock, the allergic reaction is a consequence of the union of antigen with sessile antibody which results in the liberation of histamine or histamine-like substances. Allergic shock is antagonized by histamine antagonists, such as epinephrine and ephedrine, and a number of synthetic histamine antagonists, derivatives of dialkylaminoethoxy compounds (Benadryl and Decapryn), dialkylaminoethylamines (Antergan, Antistine, Pyribenzamine, Neohetramine, Phenergan), and dialkylaminoalkyl compounds (Trimeton, Thephorin).

HYPERSENSITIVITY IN INFECTION94

Bacterial cell substance may act as a sensitizing as well as an immunizing agent, and anaphylaxis may be induced with bacterial protein, though usually with much greater difficulty than with highly antigenic proteins such as egg albumin and serum proteins. Sensitization may also occur in experimental and naturally acquired infection but is highly variable, being especially prone to occur with some bacteria and not with others.

Hypersensitivity to the tubercle bacillus is the best known of the infection hypersensitivities and is typical of them. 64 It is demonstrable as a delayed (one to four days) local inflammatory skin reaction, the tuberculin reaction, to preparations of soluble antigen of the tubercle bacillus known as tuberculin. The tuberculin reaction is considered in detail elsewhere. This kind of reaction is somewhat different from the immediate wheal type of reaction, with respect to time of development and the nature of the dermal reaction, and in that it is not passively transferable. The generalized response also differs from the immediate shock of anaphylaxis: the inoculation of a tuberculous guinea pig with tuberculin in a dose sufficient to kill does not result in death until after some hours, and on autopsy the site of inoculation is congested, focal glands are swollen and congested, and focal reactions occur about tuberculous lesions which consist of areas of enormous dilatation of the capillaries. This is obviously different from fatal anaphylactic shock in the same animal. The nature of the antigenic stimulus inducing tuberculin-like sensitivity has been shown³¹ to be a protein combined with a wax fraction of the bacilli, the protein alone giving the usual immune response with the formation of precipitins.¹⁰¹

The infection hypersensitivities differ from anaphylaxis and allergy in that they are not passively transferable by serum. This kind of hypersensitivity is, however, passively transferable; the inoculation of a normal animal with cells from an induced sterile peritoneal exudate in a sensitized animal confers the hypersensitivity on the recipient. This transfer is analogous to the adoptive immunity produced by cell transfer described above.

Hypersensitivity is the outstanding immunological response to infection with a number of other microorganisms, and the skin reactions have been of some interest from a diagnostic point of view. In brucellosis, for example, a marked degree of hypersensitivity is developed and a skin reaction, a slightly raised edematous area, appears in about six hours after the intradermal inoculation of preparations of soluble antigen of Brucella. The preparations have been given various names such as abortin (from Br. abortus), melitin (from Br. melitensis), brucellin and brucellergen. Johnin, a preparation of Johne's bacillus, Mycobacterium paratuberculosis, is used in the diagnosis of Johne's disease of cattle.

Hypersensitivity occurs with regularity in glanders, and a skin reaction intermediate between the immediate and delayed types follows intradermal inoculation of a preparation of Actinobacillus mallei designated mallein. Similarly, in chancroid a hypersensitivity develops which is demonstrable as a skin reaction following intradermal inoculation of killed Ducrey's bacillus, and a hypersensitivity occurs in leprosy which results in a positive skin reaction to extracts of leprous tissue termed lepromin.

Hypersensitivity to fungi is also not uncommon; the mycids or secondary sterile lesions which occur in some kinds of dermatophytosis are manifestations of hypersensitivity. Infection with Coccidioides

immitis and Histoplasma capsulatum sensitizes, and a skin reaction to preparations designated coccidioidin and histoplasmin is demonstrable.

Hypersensitivity also occurs in lymphogranuloma venereum, and a skin test, the Frei test, with mouse brain antigen or yolk sac culture of the responsible organism, the latter marketed as Lygranum, has very considerable diagnostic value.

THE RELATIONSHIP OF HYPER-SENSITIVITY AND IMMUNITY^{3, 71, 95}

The status of hypersensitivity with respect to effective immunity to infection has been of very considerable interest in relation to tuberculosis. It was early supposed by Koch that the development of tuberculin sensitivity was indicative of immunity, and its significance in this respect is indicated by the well-known Koch phenomenon. If tubercle bacilli are injected subcutaneously into a normal and a sensitized (i.e., infected) guinea pig, the course of the subsequent infection is considerably different. In the normal animal the usual indurated nodule forms, which becomes necrotic to form a necrotic ulcer that persists while the infection spreads via the regional lymphatics, becomes generalized, and the animal dies. In the hypersensitive animal, however, an inflammatory reaction occurs, but there is no nodule formed; within a day or two the area becomes necrotic and finally sloughs without further spread, and the shallow ulcer heals rapidly. On the other hand, the inoculation of appropriate amounts of tuberculin markedly intensifies the cellular reaction about foci of infection, and the infection tends to spread rapidly. It would seem, therefore, that within limits the hypersensitivity is functional in effective immunity, but it may also be of very great disadvantage to the host. The whole question is of particular importance in relation to active immunization against tuberculosis.

As indicated earlier, hypersensitivity may take a variety of forms. Perhaps in large part because of clinical differences, there has been some tendency to regard the allergies as basically different, not only from anaphylaxis but from one another. It will be clear, however, that there are essentially

complete analogies running through all the forms of hypersensitivity, and the differences are more apparent than real. They arise from various factors such as the portal of entry of the antigen and its effectiveness in stimulating an immunological response and the shock organ affected. Thus, there is no real difference between the atopic and nonatopic allergies that is not accounted for on the basis of the relative efficacy of the sensitizing antigen – a high degree of sensitivity is associated with ease of demonstration of antibody and interferes seriously with desensitization. since it is difficult to give enough antigen to produce an adequate desensitization. Such considerations as these are the basis of the generally accepted belief that hypersensitivity is basically the same regardless of its clinical manifestations.

It is also clear that hypersensitivity is basically an immunological phenomenon, involving the stimulation of antibody formation and the union of antigen and antibody. The paradoxical situation arising from the contrast, say, between the neutralization of toxin by antitoxin, and the acquirement of toxicity by a bland antigen, is more apparent than real and a consequence of emphasis. Bronfenbrenner has illustrated the relationship by analogy with fire: the warmth, light, and other pleasing aspects of a grate fire are also present when the house burns down; both involve precisely the same mechanism, yet the emphasis on the consequences of the combustion is entirely different in the two cases.

Chapter Sixteen

THE STAPHYLOCOCCI

The staphylococci are ubiquitous pathogenic microorganisms, are the commonest cause of localized suppurative infections, and are among the longest recognized of the pathogenic bacteria, having been characterized in the early 1880's largely through the work of Rosenbach. Nevertheless, they remain somewhat enigmatic and are less well known than the majority of bacteria. 30, 97

Morphology and staining. The coccus form tends to be much more uniform in size than the other morphological types of bacteria, and the staphylococci are consistently slightly less than 1 μ in diameter, and typically are more nearly perfect spheres than many cocci. Their most obvious morphological characteristic is their marked tendency to occur as masses of cells. This is a consequence of cell division occurring in three planes, coupled with a tendency of the daughter cells to remain in close proximity to give the characteristic appearance. These irregular clusters are three-dimensional; this is apparent on examination of wet mounts, but in the usual stained smear preparation. the clusters are flattened out to give the appearance of irregular sheets of cells. While some cells may be found singly, in pairs, or even very short chains, this characteristic morphology serves to identify the staphylococci except under special circumstances: e.g., it would be extremely difficult to differentiate staphylococci and many streptococci admixed in a smear.

These bacteria stain readily and deeply with the usual basic dyes in the simple staining procedure, and are strongly gram-positive, though rare gram-negative forms occur. They do not form spores, apparently do not have capsules except in the case of rare mucoid variants, and, although motile forms have been described, are almost invariably nonmotile.

Growth on agar mediums is abundant, and the colonies are opaque, smooth and glistening in appearance. Some staphylococci form lipochrome pigments which give the colonies a golden yellow or lemon vellow color, while others do not and are white. Although pigmentation is a variable characteristic, it is constant in primary isolates and has assumed considerable practical significance. The golden pigmented forms are Staphylococcus aureus (Staph. pyogenes var. aureus, Micrococcus pyogenes var. aureus), which are predominant almost to the exclusion of other forms in pathologic processes. The lemon yellow pigmented forms are Staph. citreus and appear to be largely saprophytic. The white forms are known as Staph. albus, with an attempt to distinguish between the varieties found on

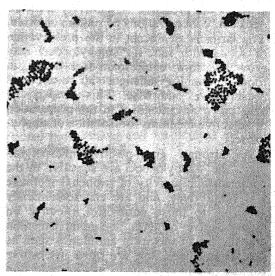

Figure 82. Staphylococcus aureus from pure culture. Note the characteristic clusters of the cocci. Fuchsin; × 1050.

the skin as a part of the normal flora as Staph. epidermidis, and Staph. pyogenes var. albus as the white staphylococci occasionally found in infectious processes; it is doubtful that such a distinction is valid or useful.

When cultured on blood agar plates, some of the staphylococci are β -hemolytic, and others are nonhemolytic; green or α -hemolysis does not appear to occur among the staphylococci. There is an approximate association between hemolytic activity and the formation of golden pigment, and the typical pathogenic form is hemolytic Staph. aureus, although nonpigmented or nonhemolytic, or both, forms are occasionally found in apparently causal relation to pathologic processes. Conversely, golden pigmented forms are not found exclusively in association with disease; some saprophytic forms are similarly pigmented.

Physiology. The staphylococci are relatively more resistant to heat, and to a certain extent disinfectants, than the vegetative forms of most pathogenic bacteria. While most bacteria are killed in 30 minutes at 60° C., higher temperatures and longer times, such as 80° C. for one hour, are often required for staphylococci. This assumes practical significance in the preparation of autogenous vaccines sometimes used in the therapy of persistent staphylococcal infections of the superficial tissues. They are also resistant to drying, may remain infectious for extended periods, and are able to grow in the presence of relatively high, 10 per cent, concentrations of sodium chloride. The latter is significant in the preservation of foods with salt, for staphylococci may grow and form enterotoxin (see below) in foods containing sufficient salt to act as a preservative otherwise. This property is also taken advantage of in the preparation of selective mediums for isolation of staphylococci.

As strongly gram-positive microorganisms, the staphylococci are sensitive to the bacteriostatic activity of triphenyl methane and other dyes, and are characteristically sensitive to those antibiotics effective on gram-positive bacteria, including penicillin and the broad-spectrum antibiotics such as the tetracyclines, but are quite insensitive to the antibiotics such as streptomycin whose antibacterial activity is confined to the gram-negative forms. They are especially prone to develop drug resistance (see

below), and some of these generalizations are frequently not applicable to current isolates.

Selective mediums. The majority of the coagulase-positive (see below) pathogenic staphylococci are able to grow in the presence of tellurite, reducing it to give graycolonies tellurite-containing black on mediums. In throat cultures on such mediums they may be confused with diphtheria bacilli, which are also resistant to tellurite and able to reduce it (Chap. Thirty). Tellurite mediums tend to be selective and have been useful in the isolation of staphylococci from heavily contaminated material such as fecal specimens. These staphylococci produce a lipase, or egg yolk factor (EYF),93 to give a zone of opacity in the medium around the colony when it contains egg yolk, and this characteristic has been combined with tellurite reduction in the development of selective isolation mediums.3,54 Mannitol (see below) and an acid-base indicator such as phenol red may be incorporated for differential, though not selective, purposes; and isolation mediums may be made selective by the inclusion of 10 per cent sodium chloride.16

Nutritive requirements. The staphylococci are not highly fastidious in their nutritive requirements, and grow readily on the usual meat extract-peptone mediums, but they grow more profusely on blood agar commonly used for isolation of the pathogenic forms. On semisynthetic mediums containing casein hydrolysate, nicotinic acid and thiamin are commonly required. and growth may be enhanced by the inclusion of additional bacterial vitamins, such as biotin, in these and simpler mediums. In chemically defined mediums, freshly isolated strains require a considerable number of amino acids, usually cystine, leucine, proline, valine, glycine, aspartic acid, phenylalanine and arginine, but the precise requirements differ from strain to strain. The bacteria can be "trained" by passage on successively simpler mediums to grow in the absence of most, or all, of the amino acids required by the parent strain.40 In general, freshly isolated strains of Staph. aureus are the most exacting in their nutritive requirements, and old laboratory cultures and Staph. albus less so.

Cultural characteristics. Lactic acid is the predominating end product of glucose fermentation, and small amounts of ethanol

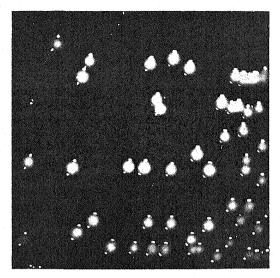

Figure 83. Colonies of *Staphylococcus aureus* on nutrient agar, 24-hour culture. × 3.

and carbon dioxide are formed. The fermentation of the conventional sugars and polyhydric alcohols is irregular and, for the most part, has no differential significance. Lactose, sucrose, maltose, glycerol, mannose, fructose, and erythritol are usually fermented; the fermentation of raffinose, inulin, and salicin is variable; and inositol. dulcitol, L-xylose, rhamnose, L-arabinose, adonitol, p-sorbitol, cellobiose, and dextrin are not fermented, and starch is not hydrolyzed. The fermentation of mannitol is considered to have differential significance in that it is fermented by the majority of coagulase-positive strains. Of the other conventional biochemical reactions indol is not produced from tryptophan, gelatin liquefaction is variable as is the reduction of nitrate. In sum, the biochemical reactions of the staphylococci, with the possible exception of the mannitol fermentation, do not provide a basis for their differentiation.

Antigenic structure. 66, 84, 85 The antigenic structure of the staphylococci of human origin has been studied in various ways, for the most part by agglutination, but also as the serological activity of soluble extracts in precipitin, gel diffusion, and passive hemagglutination reactions. Agglutination studies are complicated by the effects of blocking antigens, but these are minimized by using very young, four to six hour, cultures. Application of the conventional antigenic analysis technique has shown the presence of 30 antigens, arbitrarily designation.

nated by lower case letters, some heat-stable and some heat-labile. Typing is relatively difficult, and the slide agglutination test is considered to be much more reliable than tube titration.²¹

Soluble antigens, apparently largely carbohydrate in nature, prepared by extraction in hot dilute acid, allow the separation of the staphylococci into two groups, designated A and B; type A strains were originally thought to be pathogenic and type B nonpathogenic. It subsequently became clear that this differentiation is not clear-cut and these antigens do not occur in all strains. A protein antigen prepared by Verwey in 1940 has been reinvestigated and purified, and designated "protein A." This antigen, together with two polysaccharide antigens, polysaccharide A and polysaccharide 263, appear to be group-specific.

Attempts to correlate antigenic structure with other characteristics have not been successful. A correlation with phage type (see below) is believed by some⁸⁷ to occur, but not by others.⁸⁶ It has been suggested that serologic typing may be useful for strains untypable by phage.⁷⁰ There seems to be no correlation with virulence, and serological methods do not contribute to definition of pathogenic strains.⁴⁷

Phage typing. 12, 100 The host specificity of the bacterial viruses described elsewhere (Chap. Four) provides an additional means of characterization of bacteria, extending to strain differences. This method of differentiation was first applied to the typhoid bacillus (Chap. Twenty-one), allowing characterization within a single serotype, and has been extremely useful for epidemiological purposes. The application of bacteriophage typing, or phage typing, to the staphylococci has been largely the work of Blair and has been invaluable in providing a means of identification where the conventional biochemical and serological methods have thus far failed.

In brief, phage typing is based upon a collection of a group of phages of varied specificity but which in the aggregate will lyse the great majority of strains of bacteria encountered; these phages are numbered arbitrarily. While the maintenance of such standard typing phages requires technical precision, and test conditions must be defined, the typing procedure is simple. It is carried out by spotting the phages in appropriate dilution, and usually in two con-

centrations, on a petri dish culture of the bacterium inoculated to give a uniform film of growth. Sensitivity to phage is indicated by the clear zones of confluent lysis, grossly similar to plaques but not clonal in nature. When the bacterium is not infected by the test phage the film of growth is uniform.

Strain-specific phages are found but are rare, and phage typing is based upon a kind of spectrum or pattern of activity which is defined for the standard phages against standard test strains of bacteria. The number of such patterns is very large, impractically so, and it is recommended that for routine work a set of at least 21 basic phages should be used and grouped as follows:

Group I: 29, 52, 52A, 79, 80 Group II: 3A, 3B, 3C, 55, 71 Group III: 6, 7, 42E, 47, 53, 54, 75, 77 Group IV: 42D Miscellaneous: 81, 187

It is thus possible to characterize a strain of staphylococcus as belonging to one or another of these groups and phage types.

Such phage typing appears to be arbitrary in the present state of knowledge; *i.e.*, the nature of the susceptibility of a bacterium to infection with a bacterial virus is not yet subjected to precise definition. Among the enteric bacilli, the phage receptor on the bacterial cell may be related to the O antigen complex but, as noted above, a similar relation of contained antigen of staphylococci is quite uncertain.

Toxins. 10, 15, 75 It was apparent very early that cell-free filtrates of cultures of staphylococci are toxic on parenteral inoculation, and that extracellular toxin(s) is formed in considerable amount. The more obvious effects in experimental animals, commonly the rabbit, have been attributed to a necrotic, or dermonecrotic, toxin (dermonecrotoxin) and to a lethal toxin. In the case of the former, intradermal inoculation produces an intense inflammatory reaction, the center of the lesion becoming edematous and then necrotic about three days after inoculation. The prominent histologic feature is necrosis of the vessels, and the lesion so produced heals slowly. This activity appears to be closely similar among strains of staphylococci as indicated by protection by heterologous antiserums.

The lethal effect of the toxicity on the rabbit following intravenous inoculation may be a dramatic one. The incubation period is proportional to the dose, and may

range from as little as two minutes to as long as 24 hours with very small doses. The toxicity affects the heart directly and also the vascular supply to the lungs to give acute failure of the right heart, which is the immediate cause of death. On intracerebral or intrathecal inoculation, the toxicity acts upon the nerve cells, and death occurs very rapidly as a consequence of respiratory failure. These toxicities, and the activities of the α -hemolysin and Neisser-Wechsberg leucocidin (see below) disappear on treatment with formaldehyde to give a toxoid.

In addition to these, there are a number of other toxic activities. Among the more important are the staphylococcal hemolysins or staphylolysins; the enterotoxin; the leucocidins; and the enzymatic or kinase activities coagulase, hyaluronidase, and fibrinolysin or staphylokinase. Still other toxicities may be observed occasionally; for example, the formation of a scarlatinal or scarlatinal-like toxin has been observed, and gives a scarlet fever of staphylococcal etiology.³⁴

Staphylolysins. The pyogenic staphylococci are almost invariably hemolytic, and on primary isolation on blood agar the colonies are surrounded by a clear zone of β -hemolysis as described above. The hemolytic activity is also present in cell-free filtrates of cultures and consists of several distinct hemolysins, or staphylolysins.

The first to be differentiated were the α -and β -lysins. These differ immunologically, in the species of red cells lysed and in certain other characteristics. The α -lysin lyses sheep and rabbit red cells, but not human, guinea pig or horse cells. It requires magnesium or manganese ions and is inhibited by chelating agents.

The β -lysin acts on sheep but not rabbit cells, and has only slight hemolytic activity on human cells. It is produced by staphylococci of animal origin for the most part and is uncommon in human strains. It is also distinguished from the α -lysin in that it is a hot-cold lysin; i.e., except in very high concentrations, it does not lyse red cells when incubated at 37° C., but on chilling after such incubation the cells are lysed. It also requires magnesium ions, and the activity which disappears on treatment with chelating agents is restored by their addition.⁵⁹ In the warm phase incubation, the β -lysin potentiates the lysis of sheep cells by certain other hemolysins: that of group

TOXINS 419

B streptococci (Str. agalactiae) and the δ -staphylolysin.

A third hemolysin, the δ -lysin, differs immunologically from the α - and β -lysins, and, unlike them, lyses red cells from man, monkey, horse, rat, mouse, and guinea pig, as well as sheep and rabbit cells. 56, 57, 58 It differs also in that it reaches a peak in titer in 48-hour cultures rather than after 96 hours' incubation as in the case of the α - and β -lysins. Two other hemolysins have been described: the γ -lysin which closely resembles the α -lysin but differs immunologically and whose existence has been disputed; 30 and the ϵ -lysin which is reported to occur exclusively in nonpathogenic staphylococci.

The staphylolysins are not only hemolytic, but have other toxic activities. The α -lysin has been prepared in highly purified form, $^{8, 71}$ and the hemolytic, dermonecrotic, lethal, and leucocidal activities appear to be properties of a single substance. 67 The δ -lysin has also been found to be dermonecrotic and lethal in purified preparations. The β -lysin shows some toxicity on intravenous inoculation of rabbits, but is much less toxic than the α - and δ -lysins.

Of these staphylolysins, the α - and δ lysins predominate in strains producing disease in man and are highly correlated with the formation of coagulase (see below), more than 95 per cent of such coagulase-positive strains forming one or the other, and 82 per cent forming both. There is a similar high incidence of these lysins in coagulase-positive strains found on the skin; coagulasenegative strains from the same source do not form the α - and δ -lysins, but 95 per cent form ϵ -lysin. In contrast, α - and δ -lysins are less common in pathogenic strains of animal origin, occurring together in the absence of other lysins in only 10 per cent of strains, but the β -lysin is found in 88 per cent of such strains, and in combination with the α - and δ -lysins in 59 per cent. The incidence of these hemolysins is summarized by Elek and Levy.31

Leucocidins.⁴² The toxic effect of staphylococcal products on heterophils was observed prior to the turn of the century. Assay of this activity was put on a quantitative basis by the bioscopic method of Neisser and Wechsberg, using rabbit cells and measuring the toxic effect as the inability of the cells to reduce intracellular methylene blue, i.e., an inhibition of respira-

tion. Heterophils from man, mouse, and guinea pig are relatively resistant to this toxicity, and those from the frog almost completely resistant.

Human heterophils were used by Panton and Valentine, and the staphylococcal activity was found to inhibit phagocytosis. The Neisser-Wechsberg leucocidin is apparently identical with the α -lysin, and for all practical purposes affects only rabbit cells. In contrast, the Panton-Valentine (P-V) leucocidin, active on human as well as rabbit cells, is also antigenically distinct, and is formed by strains of staphylococcus which do not form α -lysin as well as those which do; i.e., it occurs independently. It reaches peak titer within 24 hours incubation, and is oxygen-labile and declines in titer as incubation is continued. It is separable by ion exchange chromatography¹⁰⁴ into two components, F and S, which act synergistically, and both components are antigenic⁴³ and may be toxoided with formaldehyde.41

These two leucocidins differ in their effects on heterophils. The α -lysin produces an agglutination of leucocytes and kills them as indicated by their staining with methylene blue, but the cells are not lysed. The P-V leucocidin produces a swelling of the cells to a spherical shape, with granules arranged around the periphery of the cell, and eventually the cell bursts and the granules are liberated.

A third leucocidin, designated leucolysin,⁴² has been described which differs from the P-V leucocidin in that it is thermostable, is active on the heterophils of all species tested except sheep, and is inhibited by cholesterol. It produces a nuclear swelling in the affected heterophils which are lysed in high concentrations of the activity. It is closely associated, if not identical, with the δ-lysin whose leucocidin activity had been described earlier.⁵⁵

Enterotoxin. The relation of staphylococci to the intoxication type of food poisoning described elsewhere (Chap. Twelve) was indicated by a number of observations, notably that of Barber in 1914 on acute gastrointestinal upsets associated with drinking milk from a cow with staphylococcal mastitis. It was not until 1930 that it was shown by Dack and his associates that such illness is produced by ingestion of cell-free culture of staphylococus strains which form enterotoxin.

This activity is relatively heat-stable and

unrelated to other toxicities of staphylococci. It appears to be formed only by coagulase-positive staphylococci, but not by all such strains. Enterotoxic strains are most commonly, 81 per cent of those typed, of phage types 6/47 or 42D,¹ but not all strains of these phage types are enterotoxic; the former is one of the commonest types carried by nasal carriers, and the latter a frequent cause of bovine mastitis. About 10 per cent of hospital strains were found to be enterotoxigenic in one study.⁴9 There appears to be no relation between the conventional biochemical properties of staphylococci and the production of enterotoxin.³²

Susceptibility to enterotoxin appears to be limited to man and certain monkeys. In man an acute gastrointestinal upset follows ingestion of the toxin in two to three hours and is characterized by projectile vomiting and diarrhea. Symptoms subside after a few hours, and recovery is complete.

A number of New World monkeys are susceptible and develop diarrhea and malaise, though usually not vomiting, following intragastric inoculation. The macacus monkey, Macaca mulatta, is the commonly used experimental animal. All monkeys do not respond, and susceptible animals may fail to respond after several, or even a single, such inoculation. 63 Chimpanzees have been reported to be much more susceptible.102 Purified toxin has an emetic effect on cats, presumably acting centrally,20 but the status of the kitten test for the detection of enterotoxin in culture filtrates is doubtful because peptone solutions also have a similar emetic effect.1

Enterotoxin is formed profusely in semisolid brain-heart infusion agar^{17, 38} and has been prepared as homogeneous protein with a molecular weight of 35,000 to 40,000. It is antigenic, and specific antiserum¹⁸ reacts in the gel diffusion test with as little as 1 μ g, per milliliter of purified toxin. The enterotoxin occurs as two immunological types, originally termed F and E, and now designated A and B respectively. 19 and a third, type C, has been described.7 The immunological methods are sufficiently sensitive that they may be used for the detection of enterotoxin, not only in culture filtrates, but also in appropriate extracts of foods.48 The safe

Coagulase. The ability of some bacteria, and staphylococci in particular, to

clot plasma has been described elsewhere (Chap. Nine). Staphylocoagulase has been of special interest because of its high correlation with virulence of staphylococcus strains of human and animal origin, and because of effects, such as protection of the bacteria against phagocytosis, antagonism of normal bactericidal activity of serum, etc., which plausibly relate to microbial virulence.

The activity is independent of the other staphylococcal toxins although associated with activities such as the α - and δ -lysins which also characterize virulent strains. It may be obtained cell-free although the results are somewhat erratic; the inconsistencies have been accounted for by the occurrence of bound and unbound coagulase.88 Cell-free coagulase^{33, 72} may be purified by salting out and ethanol fractionation.¹⁴ It is apparently protein in nature, containing little or no carbohydrate, and is readily inactivated by proteolytic enzymes. It is relatively heat resistant, to 60° C. for 30 minutes, and is only partially inactivated at 100° C. in the same time. It is antigenic, and serological studies28 have shown that at least four antigenic types, designated A, B, C, and D, are demonstrable; the several coagulases have been designated collectively as isocoagulases.⁷⁸ Toxoid may be prepared which is fully antigenic⁵⁰ but of, as yet, uncertain utility.

Coagulase activity in vitro is usually assayed in one or the other of two ways. One consists in mixing the bacterial culture with plasma, human or rabbit, and observing clotting. Calcium is not a factor and citrated or oxalated plasma may be used. This may be made more precise by using purified fibrinogen together with serum activator. For qualitative, and routine, purposes the plasma clumping test is used; the bacteria are suspended in a drop of plasma and coagulase-positive strains clump rapidly, giving the appearance of a slide agglutination test. The deposition of fibrin on the surface of the cells results in clumping, but the test does not precisely parallel the tube test. The presence of 1:10,000 Merthiolate, or inactivation of the plasma, interfere with the tube test but not the slide test. It has been suggested that the tube test measures free coagulase, and the plasma clumping test free or bound coagulase. Coagulase formation is also demonstrable as a halo of

alter from the control of the contro

opacity around colonies of coagulase-positive staphylococci grown on agar medium containing fibrinogen.²⁶

The bactericidal activity of normal serum toward staphylococci is markedly inhibited by coagulase,²⁹ but the mechanism of the effect is uncertain; it is apparently not concerned with the respiratory metabolism of the bacteria.¹⁰⁵ Coagulase is not highly toxic on parenteral inoculation, but in sufficient doses produces a rapid fall in fibrinogen and extensive intravenous clotting, especially in the lungs, to produce rapid death.^{13, 94}

Hyaluronidase. 69,91 This enzymatic activity, which depolymerizes the ground substance of the tissues, hyaluronic acid (Chap. Nine), is formed by the majority of pathogenic staphylococci and is thus associated with other characteristics such as α - and δ -lysin formation, coagulase production, etc. Its enzymatic activity appears to be the same as that of hyaluronidases from other sources. While hyaluronidases of different origin are serologically different, even between groups of streptococci, staphylococcal hyaluronidase appears to be antigenically homogeneous.

Staphylokinase. 68 Fibrinolytic has been studied more intensively with streptococci than with staphylococci, but a considerable portion of staphylococci isolated from human carriers and from diseased tissue will disolve fibrin clots. The mechanism of staphylococcal fibrinolysis is similar to that of streptococcal fibrinolysis described earlier (Chap. Nine) in that the bacterial product is a kinase which activates a serum or plasma protease to give the lytic activity. It differs from streptokinase in that it acts on the plasma of animal species other than man, including the dog, guinea pig, and rabbit, but not the cow, and requires a longer incubation time. It is readily differentiable from staphylocoagulase in that it is heatlabile. A curious observation reported by a number of workers is that strains of staphylococci that produce β -lysin do not produce staphylokinase.

Variation. Like other bacteria the staphylococci undergo S-R dissociation. These variants have not been thoroughly studied with respect to the various toxins described above, and available information is limited. The characteristics used to differentiate the staphylococci, viz., pigmentation, toxigenicity in the broad sense, and biochemical

activity, are all subject to variation, and are considered in connection with classification (see below).

resistance. The staphylococcal Drug variation of by far the greatest practical importance is that in susceptibility to the antimicrobial activity of the antibiotics, and has been considered elsewhere (Chap. Seven) as an outstanding example of acquired resistance. The staphylococci appear to become drug-resistant more readily than most other bacteria. They may be made resistant to antibiotics by culture in the presence of successively increasing concentrations of these substances, and they become drug resistant under natural conditions. The appearance of drug resistance in strains isolated from pathologic processes has followed the introduction of the various antibiotics into general use, and the proportion of resistant strains found has continuously increased.

Penicillin was the first antibiotic to be used, and penicillin resistance appeared shortly after its introduction, followed by resistance to the tetracyclines, erythromycin, etc. Chloramphenicol resistance occurs also, but to a lesser extent, probably because this antibiotic has been used less frequently as a consequence of its association with damage to hemopoietic tissue and the occurrence of aplastic anemia following its continued administration. Drug resistance has taken the form of multiple resistance of individual strains of staphylococci, and strains resistant to more than one antibiotic are by now the rule rather than the exception. In fact, the incidence of drug-resistant staphylococci has reached a point at which the status of treatment and control of staphylococcal infections has, in the opinion of many, essentially reverted to that of the pre-drug era. This is of particular significance in view of the increasing prevalence and fatality of these infections.

Staphylococcal infections tend to be acquired in hospitals, and the proportion of drug-resistant strains found in carriers is much higher among hospital personnel than in the general population.^{35, 95} Precise figures vary from one area to another, and change with time in a single hospital, but in general 65 to 90 per cent of strains are penicillinresistant, perhaps 50 per cent tetracyclineresistant, 20 per cent erythromycin-resistant, etc., in hospitals, while the proportions are

much lower, possibly 5 to 15 per cent penicillin-resistant, in the general population.81

Extensive use has been made of phage typing in efforts to trace the sources of infection acquired in hospitals. The phage type 80/81 appears to be the most often penicillin-resistant, but this phage type is also a prevalent virulent one (see below). Retrospective studies, by subsequent determination of phage type of earlier isolates, of strains isolated over the years 1927 through 1947¹¹ have shown that the 80/81 type (described in 1955) was prevalent in this period, but that there was a relatively low incidence of phage types of Group III, which increased after the introduction of antibiotics. Subsequently strains of Group I increased, largely at the expense of Group III.99 A new type, 83A, has appeared61 and assumed epidemic spread in some areas;27,92 it tends to be untypable because of the interfering effect of lysogenic phages.2

Experimentally, and apparently also under natural conditions, resistant strains of staphylococci tend to revert to sensitivity, illustrated in the latter instance as a reduced frequency of resistant isolates. This tendency makes possible an effective approach to the problems posed by the occurrence of resistant strains, i.e., through control of the kinds of antibiotics used for therapeutic purposes. That such control may have practical consequences is illustrated in an experience with hospital populations in which therapeutic efficacy was improved by use of antibiotics indicated by the frequency of isolation of resistant strains.⁶

Penicillin resistance among the staphylococci is of two kinds. That induced by laboratory procedures is usually accompanied by morphological changes, notably the loss of gram-positiveness, and is associated with alterations in glutamic acid metabolism described earlier (Chap. Seven), and is of a temporary character in that reversion occurs with some facility. Penicillinfast staphylococci isolated from infection, however, usually show no morphological changes, and produce penicillinase. The significance of penicillinase production, i.e., resistance by virtue of decomposing the antimicrobial agent, is underscored by the sensitivity of penicillin-resistant strains of staphylococci to 2,6-dimethoxyphenyl penicillin (Staphcillin, Celbenin, Methicillin, BRL 1241), which is not degraded by penicillinase to the inactive compound penicillinoic acid.⁶⁵ Strains are beginning to be found,⁴⁵ however, which are resistant to such "synthetic" penicillins, but the mechanism of resistance is not yet clear. Penicillins are also decomposed by penicillin acylase (Chap. Seven) of bacterial origin, but this enzyme apparently plays no significant part in resistance *in vivo*, at least in part because of its high pH optimum.

Differentiation.25 Differentiation of species or types of staphylococci has centered largely around the definition of virulence of these bacteria in terms of associated characteristics. Virulence is assessed in two ways: the source of the strain of bacteria, i.e., whether or not from a disease process, usually suppurative, in which it appears to be the primary etiological agent; and pathogenicity for experimental animals (see below). Staph. aureus and Staph. albus appear to constitute the extremes in a continuous series of types, ranging from the virulent, pigmented, toxigenic, biochemically active forms, to the feebly pathogenic, almost saprophytic, nonpigmented biochemically inactive varieties.

The correlation between coagulase activity and virulence is very high, and the terms virulent and coagulase-positive have come to be almost interchangeable. Coagulase-positive staphylococci are almost invariably pigmented, e.g., Staph. aureus, usually ferment mannitol under both aerobic and anaerobic conditions, and dextrose, maltose, and glycerol; and liquefy gelatin. The mannitol fermentation is considered by some to have differential significance because it is highly correlated with coagulase; it has been reported that about 1 per cent of coagulase-positive strains are mannitol-negative, and about 8 per cent of mannitol-positive strains are coagulase-negative.64 Coagulase-positive strains practically invariably hemolytic on blood agar, and there appears to be a high correlation between the formation of α - and δ lysins and coagulase. In one study of 532 coagulase-positive strains isolated from carriers, all α -lysin-positive strains were also coagulase-positive, and only 4 per cent of coagulase-positive strains were α -lysinnegative, and all of 100 strains isolated from suppurative infections in man were α lysin-positive. Of 200 coagulase-positive strains isolated from man and assayed by the gel diffusion method, 82 per cent produced both α - and δ -lysin, 11 per cent produced α -, β -, and δ -lysin, 3 per cent α -lysin only, and 4 per cent δ -lysin only. In total, then, 96 per cent produced α -lysin, and 97 per cent δ -lysin. It will be recalled that the α -lysin is also a leucocidin, and the δ -lysin is both dermonecrotic and lethal. In contrast, of 77 coagulase-negative strains, none produced α -, β -, or δ -lysins, but 95 per cent produced ϵ -lysin, and the remainder were not hemolytic. On the basis of information such as the foregoing, then, it is possible to define tentatively a virulent staphylococcus as one that is coagulase-positive and produces α - and/or δ -lysins.

Classification.4,5 The formal classification of the staphylococci is, like that of many other bacteria, not completely satisfactory. Most workers accept three general groups of these organisms: (1) the Staph. aureus-Staph, albus series of strains or types with species status of the two extremes, virulent Staph. aureus and the relatively avirulent Staph. albus of the normal flora of the human skin, mouth, and upper respiratory tract; (2) a group of saprophytic staphylococci found in air, milk, etc., and including the lemon-yellow pigmented Staph. citreus, varieties forming pink to reddish brown pigments, and colorless forms closely resembling Staph. albus; and, (3) a group of obligate anaerobic staphylococci which are among the normal flora of the human body cavities, and one of which. Staph. aerogenes, is occasionally a cause of puerperal sepsis.

Pathogenicity.³⁰ Except in the case of staphylococcal pneumonias, these microorganisms enter the body either through the intact skin or following breaking of this barrier by trauma. The route of infection into the intact skin appears to be the hair follicles or sweat ducts. The staphylococcal infections commonly assume a localized form with a focus of purulent infection partially or completely walled off from surrounding tissues. This may be limited or may spread via the blood stream to give rise to secondary foci of infection in whatever tissues or organs the bacteria may lodge. Occasionally the infection may assume a fulminating bacteremic form.

The character of these infections is attributable, at least in part, to the properties of the toxic products of the microorganism. The close association of virulence with the formation of coagulase and the α - and δ -lysins allows a partial explanation of the

pathogenesis of the infections produced. It seems probable that the tendency of the focus of infection to be walled off can be attributed to the action of coagulase, and the purulent character of the lesion to the necrotic activity and killing of locally mobilized leucocytes by the α - and δ -lysins, 53 although an association of α -lysin with virulence under experimental conditions has been questioned.37 The deposition of fibrin on the surface of the bacteria appears to interfere with phagocytosis, and even phagocytosis, coagulase-positive after staphylococci tend to persist in viable form. 22, 76 The development of metastatic abscesses or focal infections, as in the bone giving rise to staphylococcal osteomyelitis, is a consequence of hematogenous spread of the infection in the form of thrombi and phagocytic cells containing viable microorganisms.

Pathogenicity for man. 74, 77, 90 Staphylococci are constantly present on the skin and in the upper respiratory tract. These are commonly the relatively avirulent Staph. albus, but virulent Staph. aureus occurs, especially in the upper respiratory tract.

CARRIERS. Nasal carriers are probably the most important single reservoir of staphylococcal infection of man.83, 101 increasing significance of infection with antibiotic-resistant staphylococci has resulted in a resurgence of interest in the carrier and the control of carrier-disseminated infection.⁷³ The spread of infection, airborne or by contact, is of particular concern in surgical wards and in maternity wards. The former is a prolific source of staphylococcal wound infection, and in the latter the newborn become infected within the first few days of life, and show a rate of perhaps 90 per cent on discharge. The infection rate in hospitals in this country has been found to be 9 to 13 per 10,000 patient days.³⁹ Examination of available data for the Scandinavian and Commonwealth countries and the United States over the period 1937-195980 has shown wide fluctuation in the carrier rates, from 20 to 60 per cent approximately, a reflection of the entry of penicillin into general use in the 1940's, and no general tendency to reduction; e.g., rates of 40 to 50 per cent are recorded for 1959.

SUPPURATIVE INFECTIONS. A transitory drop in resistance may be sufficient to allow local invasion and the establishing of a focus

of infection, perhaps acne or a simple boil, pemphigus or impetigo neonatorum, or a more or less extensive carbuncular condition may develop, possibly followed by the appearance of metastatic abscesses or bacteremia. Whether a focus of infection is initially established following penetration of the mechanical barrier, and the course of events following its establishment, are functions of the balance between the virulence of the microorganism and the natural immunity of the host. Thus a variety of lesions and diseases of the skin are of staphylococcal etiology, as are a large majority of cases of osteomyelitis and periostitis, many cases of otitis media and sinusitis and, much less often, urinary tract infections and the relatively rare staphylococcal meningitis. In general, suppurative inflammation, in whatever part of the body it may occur, is usually associated with the presence of staphylococci either in pure or mixed culture. When they occur in mixed infections, staphylococci may represent either primary or secondary invaders: it is often impossible to determine the sequence of events.

ENTERITIS.51 Staphylococcal enteritis came into increasing prominence with the general use of antibiotics, especially the broad-spectrum antibiotics given by mouth. Such therapy, or prophylaxis, favors the growth of resistant staphylococci in the bowel at the expense of the normal flora: staphylococci occur frequently in the bowel and are readily detectable in 10 to 15 per cent of persons with no enteric disease. The disease occurs more commonly in surgical patients given prophylactic antibiotic therapy. The severity of the enteritis is approximately related to the relative numbers of staphylococci present, and in severe cases the intestinal flora may be grossly abnormal, almost completely lacking in gramnegative bacteria and consisting largely of enormous numbers of staphylococci admixed with pus cells as observed in fecal smears. On autopsy, the enteritis is usually found to be a pseudomembranous type. It is not clear what part staphylococcal toxins, such as enterotoxin and the staphylolysins. play in the pathogenesis of the disease, or the role, if any, of staphylococci in ulcerative colitis. This kind of enteritis is to be distinguished from staphylococcal food poisoning (Chap. Twelve), although it is probable that the enterotoxins play a part in its pathogenesis.

PNEUMONIA.^{36, 46} Pneumonias of staphylococcal etiology, while not common, appear to be increasing and to be displacing a portion of pneumococcal and streptococcal pneumonias in pneumonia mortality,23 probably as a consequence of the continued susceptibility of the last two to antibiotics and the markedly increased prevalence of antibiotic resistant staphylococci. Staphylococcal pneumonias are probably almost always secondary, often to influenza;89 the alveolar edema of influenza is thought to favor staphylococcal infection. Two general types are recognized. One is a gradually developing cavitating pneumonia in which the initial lesion is a diffuse pulmonary mottling which coalesces to give consolidation and cavity formation. The other is a fulminating hemorrhagic pneumonia profound toxemia and is often accompanied by bacteremia. This second type is often secondary to influenza, and occurs in infants. 103 The bacteria may be found, frequently in almost pure culture, in sputum, empyema fluid, or lung puncture specimens, and in the blood when there is bacteremia. Intratracheal or intrabronchial inoculation of rabbits with cell-free filtrates has been found to result in consolidation, peribronchial areas of hemorrhagic congestion and necrosis, and blood vessel damage leading to ischemia of large areas of lung, a picture considered similar to that found in early cases of staphylococcal pneumonias in man.60

PREVALENCE. 60 Staphylococcal infections have increased in prevalence and fatality, practically displacing the pneumococcus as the immediate etiological agent in terminal infection, and these infections, together with tuberculosis and enteric infections, have become the predominant bacterial infections in this country. Epidemiological studies have shown that there is a marked association between particular phage types and virulence as inferred from the source of the strain.9 A large portion of virulent strains, to as much as 40 to 90 per cent in a given hospital, belong to the 80/81 complex. This complex includes strains which are also lysed by 52 and 52A phages, and the complex may be taken to include 80, 81, 80/81, 80/81/52/52A, and 80/ 52/52A.82 There is no evidence that the staphylococci have become more virulent; in fact, primary hematogenous osteomyelitis has declined in incidence. It is more probable that these infections have increased at the expense of others more susceptible to chemotherapy, and it is possible also that factors such as skin punctures for diagnostic purposes and the more general use of x-ray and cortisone may have contributed to a reduced resistance to infection with these microorganisms.

Pathogenicity for animals.^{24, 79} While man is considerably more susceptible to infection with staphylococci than the lower animals, naturally occurring enzootic infections in domestic animals are well known. and experimental animals may be infected. In horses and cattle Staph, aureus is associated with pathological processes and conditions similar to those it produces in man. Staphylococcal mastitis in cattle is not uncommon; the cattle are often infected by man, or the infection is carried from one cow to another by the milker, and infected cattle constitute a minor source of human infection. Staphylococcal infection of lambs is associated with tick bite and assumes an acute and a chronic form; the first is bacteremia with death occurring within 24 hours, and the second is characterized by the development of metastatic abscesses. Staphylococci have also been isolated from naturally occurring abscesses in birds.

Of the experimental animals, the rabbit is one of the most susceptible.44,62 Intravenous inoculation of 0.1 ml. of a 24-hour broth culture produces an infection that is fatal in four to eight days, and on autopsy abscesses are found in various organs, most commonly in the cortex of the kidney and in the walls of the heart. Usually infection does not occur in the bone marrow or periosteum, but it has been reported that osteomyelitis may be produced in young animals. If the bone is fractured or the periosteum is injured prior to inoculation, however, a sequence of events closely similar to osteomyelitis in man is produced. Ocular infections may be produced, but intraperitoneal infection is relatively unsuccessful. The mouse also is resistant to intraperitoneal inoculation, but following intravenous inoculation with approximately 40 million microorganisms, about 85 per cent of the animals die, and on autopsy abscesses in the kidney are the characteristic finding. Of the other common experimental animals, the guinea pig is relatively resistant to infection with staphylococci, and the rat and pigeon are highly resistant. In general, there seems to be no satisfactory animal test for the virulence of staphylococci.

Bacteriological diagnosis. The isolation of staphylococci is usually not a difficult matter. Blood agar is the medium of choice for isolation of the organism from purulent specimens, and on 24 hours' incubation Staph. aureus gives good growth of creamy, deeply pigmented colonies that are surrounded by the clear zones of β -hemolysis. The staphylococci are able to grow in the presence of 7.5 per cent sodium chloride, which is inhibitory to many bacteria, and selective mediums containing salt together with mannitol and sometimes phenol red as an acid-base indicator have been used for the isolation of staphylococci from specimens heavily contaminated with other bacteria.52,98

Examination of Gram-stained smears from typical colonies will show the characteristic morphology, and the coagulase test is routinely carried out, usually as the slide test in which the bacteria are suspended in plasma and observed under the microscope for clumping. Biochemical reactions, with the possible exception of mannitol fermentation and gelatinase formation, are uninformative. Differentiation of the lysins is carried out only for special purposes and most simply by inclusion of appropriate antiserums in a blood agar medium. The presence of enterotoxin in epidemiologically implicated foods, or the enterotoxigenicity of isolates, may be demonstrated immunologically by application of the gel diffusion test and specific antiserums as described above.

Immunity. Acquired immunity to infection with staphylococci is generally of a low order. Both natural and acquired immunity appear to be primarily cellular in nature, with phagocytosis of the microorganisms as the most significant factor. As pointed out above, the close association of coagulase with virulence suggests that this activity is an important element in the pathogenicity of the microorganism, but it is a poor antigen, stimulating only an irregular and low-grade immune response. The staphylolysins are good antigens, however, and the immune response to these and P-V leucocidin may account for the observations that antileucocidin is a significant part of effective acquired immunity. In addition, the nature of the infectious process is such as to minimize contact of the staphylococcal

antigens with both the antibody-forming cells and the circulating antibody. Microorganisms present in the abscesses produced by these bacteria are effectively separated from the blood stream; it is well known, for example, that staphylococcal osteomyelitis even of long standing does not result in an effective immune response, and, conversely, such lesions are not affected to an appreciable extent by circulating antibody or by drugs. Even on hematogenous spread of infection with the formation of secondary abscesses, many of the viable staphylococci are protected to a certain extent from antibody that may be present in the blood, for they are contained in leucocytes or within masses of fibrin.

Active immunization procedures, making use of vaccines, often autogenous, or cell-free filtrate containing staphylolysins tox-oided by treatment with formalin, are usually carried out on a therapeutic rather than prophylactic basis. Skin infections, such as pustular acne, are frequently difficult to treat, and active immunization has been of interest as a therapeutic measure. In general encouraging, though not striking, results have been obtained but may not appear for some months. The therapeutic use of antiserums has given disappointing results.

Chemotherapy. Sensitive strains staphylococci are susceptible to the antibacterial activity of the sulfonamides, penicillin, the tetracyclines, chloramphenicol, erythromycin, and other antibiotics active on gram-positive bacteria. The 80 per cent case fatality rate in staphylococcal septicemia was reduced to about 30 per cent with the introduction of penicillin, but subsequent development of drug-resistant strains has increased this over-all figure to 50 per cent or more. The problem of chemotherapy, of staphylococcal infections is, therefore, complicated by the prevalence of resistant strains, and strains of multiple resistance, and resistance to new antibiotics develops rapidly as they come into use. It is essential, therefore, that strains isolated from pathological processes be tested for sensitivity to a variety of potentially effective agents as a part of routine diagnostic procedure so that a basis for rational and effective chemotherapy may be provided.

When the strain is sensitive to an available chemoterapeutic agent, chemotherapy of staphylococcus bacteremia is strikingly successful, of localized infection in the form

of abscesses less so, and of osteomyelitis not at all without adequate surgery. In the last two, the microorganisms are partially or practically completely protected from the drug.

OTHER MICROCOCCI 96

A variety of micrococci, both pigmented and otherwise, have been described, most of which are saprophytic forms found in water and elsewhere in nature. A well-known representative of this group is *Sarcina lutea*, a coccal form producing a bright yellow pigment which derives its generic name from a tendency to form cubical packets of eight cells.

Micrococcus tetragenus (Gaffkya tetragena) is a parasitic coccus frequently found on the mucous membranes of the upper respiratory tract. It was discovered by Gaffky in 1881 in the pulmonary cavities in phthisis and has been found in pure culture in abscesses in animals and man, and often occurs in the healthy mouth. It is not uncommonly found in suppurations of the mouth and neck. It is also found in the empyema following pneumonia and in the pus of war wounds. This microorganism is probably of low-grade virulence and unable, as a rule, to invade the human tissues except

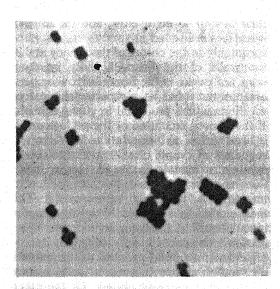

Figure 84. Micrococcus tetragenus; smear from pure culture stained with fuchsin. Note the relatively large size of the cells and the typical tetrad arrangement with the irregular clumps tending to be made up of tetrads. \times 1800.

when the resistance is lowered by some depressing influence, especially of the kind caused by the invasion of some other bacterium. White mice inoculated with *M. tetragenus* succumb to a rapidly progressing septicemia. Guinea pigs and rabbits usually show only a local affection. House mice and rats are relatively resistant.

Morphologically *M. tetrangenus* is distinguished by its occurrence in tetrads or groups consisting of four small oval cocci. It is gram-positive. In cultures the sheetlike arrangement is not always seen, but in the animal organism the flat tablets occur uniformly, and a rather heavy capsule surrounds the tetrad. On agar a confluent rough, elevated white growth is produced. Gelatin is not liquefied; milk is coagulated. Growth is slow and occurs at 20° and at 37° C., though better at the higher temperature.

Chapter Seventeen

THE STREPTOCOCCI

The streptococci make up a relatively large group of pyogenic coccus forms characterized by an arrangement of the cells in chains. They are responsible for a variety of diseases of man and certain diseases of lower animals, and some are saprophytes found in milk and milk products. They were early observed in the pus formed in suppurative inflammatory conditions, and their frequent presence and pathological significance were first emphasized by Ogston, by Fehleisen, and by Rosenbach in the early 1880's. It is now well known that, in addition to the more virulent pathogenic forms, relatively harmless parasitic streptococci are more or less constantly present in the human throat and in the intestinal tract which assume a pathogenic role only under circumstances in which normal resistance is markedly reduced, and which may be regarded, for all practical purposes, as a portion of the normal flora of the human body.

Morphology and staining. Like staphylococci, individual streptococci are spherical and 0.8 to 1.0 μ in diameter. Some variation in size results from the character of the culture medium, and the individual cells are frequently appreciably smaller when the cultures are grown under anaerobic conditions. Smaller varieties, 0.4 to 0.8 μ in diameter, whose size is apparently a constant character, have been described. The typical streptococcus divides in only one plane, and the tendency of the cells to remain united results in the development of the characteristic chains that give these organisms their generic name. This tendency is apparently more pronounced between daughter cells following the first cell division, and the chains frequently have the appearance of chains of diplococci, with pairs closer to one another than to adjacent pairs. The firmness of the attachment is to some degree a strain characteristic, and some strains appear as relatively long chains while others show little more than two pairs of diplococci.

Earlier workers attached some importance to the length of chains formed and differentiated a supposedly more virulent Streptococcus longus and a less virulent Str. brevis. This distinction has little meaning, in spite of the fact that freshly isolated streptococci from pathological processes usually form chains of more than eight cells while those normally present in the mouth and throat usually develop only short chains. For instance, longer chains are generally formed during growth in liquid mediums; Str. lactis, a common inhabitant of milk, forms very long chains, and short-chain streptococci are not infrequently isolated from pathological conditions. The formation

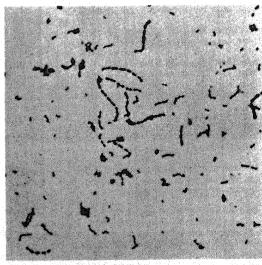

Figure 85. Streptococcus pyogenes. Recently isolated scarlet fever strain. Note the tendency to diplococcus arrangement in the chains. Fuchsin; × 1050.

PHYSIOLOGY 431

of chains of cells is in no sense absolute, however, and on microscopic examination of a smear of typical streptococci, single cells, pairs of cells, and occasional aggregates resembling staphylococci are found.

Streptococci are not motile under ordinary conditions of observation, but motile forms have been described from time to time.³⁴ The majority of strains are encapsulated, and in some the capsular material consists of hyaluronic acid, the substrate of hyaluronidase. So far as is known, these bacteria do not form spores, and the formation of pigment is relatively rare.

They stain readily with the usual bacterial stains. Almost all of the strains isolated from pathological processes in man are gram-positive, but gram-negative strepto-cocci are found, more commonly in suppurative conditions in lower animals than in man.

Streptococcus colonies on agar mediums are usually quite small, translucent, convex, entire, and slightly granular. The colonial form designated matt, with a ground-glass rather than a glistening or glossy surface, is the virulent form of β -hemolytic streptococci commonly encountered on primary isolation from infectious processes, but variant forms occur also (see below).

Physiology. As a group, the streptococci grow over a relatively wide temperature range, 10° to 42° C. Those of the pyogenic group, which is made up of human and animal parasites, have an optimum at 37° C. and are relatively restricted in range; those of the lactic group grow over 10° to 37° C.; and the viridans group grows from 37° to 42° C. and includes one thermophilic species which grows at 50° C. The majority of streptococci are facultative anaerobes, but there are a few obligate anaerobic varieties.

The streptococci are among the more fastidious of bacteria with respect to nutritive requirements. They will usually not grow on meat extract mediums, and growth is ordinarily poor even on infusion mediums but may be somewhat improved by the inclusion of phosphate buffer and a small amount, perhaps 0.1 per cent, of glucose. For the most part infusion mediums enriched by the addition of 10 per cent defibrinated blood, ascitic fluid, and similar substances are used, and a medium such as blood agar is satisfactory for routine culture of the pathogenic forms. Many strains are hemolytic on blood agar, some showing

the clear zones of β -hemolysis, and others a zone of greenish discoloration or α -hemolysis indistinguishable from that produced by the pneumococcus. Growth also occurs in milk which is curdled by some species because of the fermentation of lactose.

Streptococcus cultures may be preserved in serum broth or agar or infusion gelatin stabs in the refrigerator.

The relatively complex nutritive requirements of these bacteria have been defined to a considerable degree. Most strains require glutamine, riboflavin, pantothenic acid, pyridoxine, nicotinic acid, and biotin, together with 13 or 14 amino acids. The streptococci of group A also require nucleic acid derivatives. Some strains have been cultivated in mediums containing albumin or casein hydrolysate, supplemented with various amino acids and vitamins, and others in chemically defined mediums.⁵⁹

A wide variety of sugars are fermented and a number of polysaccharides are hydrolyzed. The chief fermentation product of glucose is lactic acid, and small amounts of formic and acetic acids and ethyl alcohol are formed. The hydrolysis of sodium hippurate and polymers such as inulin, starch, and dextrin has some differential significance, together with the fermentation of lactose, sorbitol, glycerol, mannitol, maltose, sucrose, and raffinose. Some strains liberate relatively large amounts of ammonia from peptone, and this characteristic also has some differential value. With rare exceptions, inulin is not fermented nor are the streptococci dissolved in ox bile or a 10 per cent solution of bile salt; these characteristics have considerable practical importance in that they serve to differentiate the α -hemolytic or green streptococci from the pneumococci.

The formation of toxic substances. The hemolytic streptococci produce a number of toxic substances. Certain of these appear to be intracellular and are found in sonic lysates of the bacteria, while others diffuse from the cells and are found in cell-free filtrates. In the former group, an intracellular hemolysin is formed which is demonstrable in sonic lysates⁸³ is distinct from the extracellular streptolysins (see below), and is lethal for the mouse.⁸⁶ Intracellular substances which are pyrogenic, produce rash, and give nodular lesions in the dermal connective tissue of rabbits have been studied at length.^{12, 14, 105} These activities appear to

be associated with the cell wall⁷⁷ and contain active polysaccharide,81 but are differentiated from the endotoxins of the gram-negative bacilli.11

The extracellular toxic activities include the streptolysins or hemolysins, streptokinase, hyaluronidase, the erythrogenic or scarlatinal toxin, leucocidin which kills heterophils that have ingested the bacteria, and possibly an enterotoxin in the case of certain of the α -hemolytic streptococci which are an occasional cause of foodpoisoning.63

Streptolysins. Two kinds of filterable hemolysin produced by streptococci were distinguished by Todd. They differ in that one, called streptolysin S, is sensitive to treatment with heat or acid, and the other which is designated streptolysin O, is inactivated by oxygen, i.e., is inactive in the oxidized state, and the activity may be restored by treatment with mild reducing agents such as sulfite. Both hemolysins are extremely labile at 37° C. and disappear rapidly after the first few hours of incubation.

Streptolysin O appears to be much the more important to the virulence of the hemolytic streptococci, and has a specific cardiotoxic activity which has been described by Bernheimer and his associates.5, 6, 43 Inoculation of the toxin results in the release of inhibitor, lipoprotein in nature, from the heart muscle of the frog resulting in sensitivity to the cardiotoxic action, and which is also released to occur in the serum albumin fraction and inhibits hemolysis in vitro.80 There is also evidence that streptolysin O has leucocidin activity. This toxin is antigenic, and antibody to it is regularly formed in streptococcal infections; the antibody titration has been put upon a standardized basis.25,98

Streptokinase.98 The hemolytic streptococci of Groups A, C, and G (see below) produce streptokinase, the plasmin activator that initiates the fibrinolytic dissolution of fibrin clots (Chap. Nine). It is most actively produced by strains of Group C and only irregularly and to low titer by strains of Group G. No special cultural conditions seem to be required for the production of the activity. There is some species specificity in that human, dog, and rabbit plasminogens are readily activated, but those of pig. horse, and cow are less readily activated, and guinea pig and sheep plasminogens are not activated by the usual concentrations of streptokinase. The activity is antigenic and antibody is produced, seemingly irregularly, in infected persons. The titration of the antibody is complicated by variation in the antiprotease and lytic factor concentrations in the test plasma, and, more important, streptokinase is not immunologically homogeneous and that produced by different strains of streptococci is often antigenically different. 107 Titration of such antibody levels has little significance in practice.

Hemolytic streptococci also produce streptodornase, a deoxyribonuclease which is apparently unrelated to virulence. It is not homogeneous, even within a single streptococcal strain, and has been separated electrophoretically into three components, A, B, and C; the last is inhibited by citrate and all three by chelating agents. 104 Streptokinase and streptodornase are available as commerical preparations (Varidase) for clinical application in the enzymatic debridement of necrotic tissue and dissolution of fibrous exudates.1

Hyaluronidase. The majority of hemolytic streptococci produce hyaluronidase, the enzymatic activity of which depolymerizes the gound substance of the tissues (Chap. Nine). Strains isolated from healthy throats produce as much hyaluronidase as those from mild or severe infections. The capsular substance of encapsulated strains of hemolytic streptococci of both Groups A and C consists of hyaluronic acid and such strains do not produce hyaluronidase although they are usually virulent. It is a plausible supposition that the production of this activity may be causally related to the ability of virulent streptococci to spread within the tissues, and in fact the production of hyaluronidase is increased in the presence of the substrate. The virulence of encapsulated strains and the lack of direct experimental evidence would seem to invalidate such an assumption. On the contrary, the production of hyaluronic acid, e.g., capsules, while apparently unimportant to experimental infection by the intraperitoneal route, appears to be essential to infection by inhalation. 15. 87

Erythrogenic toxin. The erythrogenic toxin is a substance which gives rise to a marked local erythema upon intradermal inoculation in man, and in larger amounts produces a generalized erythematous rash. A skin reaction may be produced in the rabbit, but, in general, laboratory animals are highly or completely resistant to it. The lethal dose for the rabbit is very large, 5 to 10 ml. of unconcentrated filtrate. This toxin is responsible for the rash of scarlet fever and is known as "scarlatinal toxin," or "Dick toxin" after its discoverers. It differs from the classic exotoxins in that it is relatively heat-resistant and some toxicity still remains after boiling for 30 minutes. It is antigenic and stimulates the production of specific antitoxin but not to the high titers readily obtained for diphtheria and tetanus antitoxin.

The formation of the foregoing substances by the streptococci is a characteristic of the group rather than of all strains of pathogenic streptococci. Thus all group A streptococci do not, produce erythrogenic toxin, and those that do not are incapable of causing scarlet fever. In general they are associated with virulence in that avirulent varieties are frequently nonhemolytic, nonfibrinolytic, and the like, while those found in pathological conditions and showing high virulence under experimental conditions are hemolytic, fibrinolytic, etc.

Hypersensitivity. Another factor associated with the ability of streptococci to produce disease is the development of a hypersensitivity to the cell substance of these bacteria during the following infection. Subsequent infections, then, result in allergic phenomena which may be of considerable importance in the disease produced. It seems probable that hypersensitivity plays a part in rheumatoid disease and arthritis of streptococcal etiology (see below).

Variation. Alterations in the morphology of individual streptococci are frequently observed in old cultures, with cells swollen to several times normal size. These and other changes in aging cultures have been interpreted by some workers as indicative of a complex life cycle, but it is more likely that such aberrant morphology is that of involution forms, *i.e.*, is degenerative in nature. The streptococci may, under appropriate conditions, occur as L forms and protoplasts.²⁴ These occur in Group C as well as Group A hemolytic streptococci.

Dissociative changes in colonial morphology are well known. A form designated as matt is the virulent form and distinct from the usual smooth and rough colony types. A mucoid colony type has been described which was still different. There are,

then, four recognized colonial types: smooth (glossy), rough, mucoid, and matt. The conversion from mucoid or matt to rough or smooth corresponds to the usual $S \rightarrow R$ dissociative change. The M antigen is present in the matt colony type, in fact derives its name from the association, but is deficient in the smooth glossy colonial type. Exceptions are not uncommon, and colonial morphology appears to be determined primarily by capsule formation; i.e., mucoid or matt colonies are formed by encapsulated streptococci and the smooth, glossy colony by strains which do not form them; the occurrence of M antigen is associated with capsule formation rather than contributing to colonial type. 114 Other immunological variation, not correlated with colonial form, may occur also, for there is some evidence that the agglutinative types are sometimes unstable and that on occasion the groupspecific polysaccharide may be lost (see below).

Variation in hemolysis is commonly reported in which β -hemolytic strains give rise to nonhemolytic or α -hemolytic variants. The alteration in hemolysis is to some degree an environmental effect in that anhemolytic variants may be hemolytic under anaerobic conditions, suggesting an inactivation of oxygen-labile hemolysin rather than failure to produce it; similarly α -hemolytic variants may be made β -hemolytic by including catalase in the medium or omitting reducing sugar, since the latter appears to inhibit hemolysin production by some strains of streptococci. Streptolysin O is generally regarded as responsible for blood plate hemolysis, but anhemolytic variants of β hemolytic strains have been observed which continue to form streptolysin O in liquid culture.

Drug resistance. Streptococcal infections are successfully treated with sulfonamides, penicillin, and the broad-spectrum antibiotics but may become resistant to these agents. Resistance may be induced experimentally in the usual way, and drug-resistant strains have been found to occur under natural conditions. As a group, the streptococci are much less prone to become resistant under natural conditions than are the staphylococci, and strains of acquired drug resistance do not occur often enough to present any practical problem. Although the β -hemolytic streptococci are relatively uniform in their susceptibility to the chemo-

therapeutic drugs, the α -hemolytic forms vary widely, but as a strain rather than an induced characteristic.

That resistant strains may occur on a relatively large scale was demonstrated during World War II, when sulfadiazine was used for the prophylaxis of streptococcal infection in certain military training camps.³¹ The resistant strain, or strains, that emerged spread in the military population and into the civilian population, but with discontinuance of the general use of sulfonamides when penicillin, and subsequently other antibiotics, became generally available, sulfadiazine resistance became of no importance and seems to have disappeared. On the other hand, the widespread use of penicillin, both generally and for the prophylaxis of rheumatic fever (see below), has not been accompanied by the general appearance of penicillin-resistant streptococci.

Classification. 87,88 The differentiation and identification of the streptococci is a matter of very considerable practical importance because of their etiological relation to a number of widespread diseases of man and domestic animals and, of equal importance, from the theoretical point of view. It has been and continues to be a particularly difficult matter, since neither the physiological nor immunological methods have been satisfactory. As a consequence there is basic disagreement among workers in this field as to what constitutes a species or variety and on what basis or bases differentiation should be made. Three general criteria have been used, viz., hemolysis on blood agar plate culture, biochemical properties, and immunological character as indicated by precipitin and agglutination reactions. Those concerned with the pathogenic streptococci make a tentative preliminary separation on the basis of hemolysis and define species and types on an immunological basis. Workers with more general interests tend to rely primarily on physiological characters, and this is the basis of the Bergey classification.

Hemolysis. The use of blood plate hemolysis was introduced by Schottmüller in 1903 and is especially convenient since blood agar is the medium of choice in primary isolation. On this basis three types of streptococci may be distinguished:

(1) The β -hemolytic streptococci, which produce a clear zone of hemolysis in the red opaque medium immediately surrounding the colony

(2) The α -hemolytic or green streptococci, which produce a zone of greenish discoloration in the medium about the colony which is considerably smaller than the clear zone of β -hemolysis

(3) The anhemolytic, indifferent, or γ streptococci, which produce no change in the medium

These distinctions have some validity in that the highly virulent streptococci isolated from pathological conditions are almost invariably the β -hemolytic variety. In the older literature these are grouped as a single species with the name Str. hemolyticus, and some workers further differentiated on the basis of the disease with which the strain was associated, viz., Str. scarlatinae (scarlet fever) Str. epidemicus (epidemic septic sore throat), Str. erysipelatis (erysipelas), etc. It is now quite clear that these distinctions are invalid in that identical streptococci may cause more than one clinical disease and that the same disease may be caused by immunologically distinct streptococci. At the same time, antigenic types of streptococci may be associated with one or another manifestation of streptococcal infection. such as the association of type 12 with acute glomerulonephritis; whether such associations as have been observed are more than fortuitous is not clear.

The β -hemolytic streptococci associated with diseases of lower animals do. however,

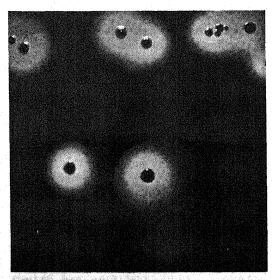

Figure 86. Streptococcus pyogenes. Pure culture on blood agar showing β -hemolysis. \times 5.

And Allert Thoracatalastic state

show a high degree of specificity in the case of *Str. equi*, causing strangles in horses, and *Str. agalactiae*, causing mastitis in cattle, but not in that of the organism now known as *Str. zooepidemicus*, which causes a wide variety of suppurative diseases in animals, including mastitis in cattle.

The β -hemolytic streptococci of human disease are usually not found in lower animals, but may occasionally infect the udder of the cow, giving rise to milkborne streptococcal infection. Conversely, those of animal origin do not ordinarly infect man, though human infections with Str. zooepidemicus, while not common, are somewhat more so than is generally believed. An even greater heterogeneity in the group is indicated by the fact that some nonpathogenic forms are also β -hemolytic. It is clear that the inclusion of all these forms under the single species Str. hemolyticus is not justified.

A somewhat similar situation holds true with the α -hemolytic or green streptococci which have been grouped as a single species, Str. viridans. The green-producing group embraces such forms as the fecal streptococci or enterococcus group, those which normally inhabit the mouth and throat, and nonpathogenic forms. Some of the α hemolytic forms, especially those found in the throat and intestine, are able to set up disease processes if normal resistance is reduced, with the production of localized infections at the roots of teeth, in the heart valves in bacterial endocarditis, and other locations. These pathogenic forms differ rather sharply from the highly virulent β hemolytic streptococci, but again the entire group is too heterogeneous to justify inclusion in a single species.

The anhemolytic or indifferent streptococci are almost all saprophytic forms found in milk and various dairy products. The only pathological condition with which they have been unequivocally associated is subacute bacterial endocarditis,⁷⁸ in which they have been found in a small minority of cases. Here a variety of physiologically different types are included in a single group, and, as in the case of the other groups separated on the basis of hemolysis, it is too heterogeneous to allow lumping into the single species, *Str. anhemolyticus*.

Immunological differentiation. Largely

through the work of Lancefield and her coworkers, the pattern of antigenic structure of the β -hemolytic streptococci has been defined, but the viridans and anhemolytic forms are serologically diverse so that this approach has not been useful. By the extraction of soluble antigens and application of the precipitin test, Lancefield has demonstrated the presence of both group-specific and type-specific antigens in the hemolytic streptococci. The group-specific antigen, or C substance, is polysaccharide in nature and an integral part of the bacterial cell89, 90 rather than a capsular material, and is reported82 to be toxic in appropriate state of dispersion. On the basis of the specificity of this antigen five groups were originally described and designated Group A, Group B, and so on; additional groups have since been found, up to and including Group N. The biological singificance of these groups is indicated by the origin of the strains making them up, viz.,

Group A-Primarily pathogens of man

Group B-Found almost entirely in mastitis of cattle Group C-Primarily pathogens of lower animals

Group D-Found in cheese

Group E-Found in milk

The association of origin and immunological group is, however, not absolute. Streptococci of Group A are occasionally found in lower animals, producing mastitis in cattle

for example, while those of Group C are found in man with some frequency as indicated in the accompanying table.

Type specificity among the streptococci was also indicated by the work of Griffith, who separated β -hemolytic streptococci isolated from human disease into 27 types by slide agglutination, and later added three more types. These were given arbitrary Arabic numbers, viz, type 1, type 2, etc. Following definition of the serological groups of Lancefield, it was found that these types are distributed over the groups; Group A included the majority, 23 in all, and types 7, 20, and 21 fell into Group C, and type 16 into Group D. 16

Lancefield has shown that the types within Group A are determined by two type-specific antigens. One of these, the "M" antigen, is a nucleoprotein located apparently very superficially in the cell wall.²⁷ It is destroyed by proteolytic enzymes, and may be digested by a soluble protease produced by streptococci, resulting in strains which cannot be typed by "M" antiserums. It has been purified to electrophoretic homogeneity but still contains non-type specific protein antigen.⁴⁸

The other type-specific antigen, designated the "T" antigen, is not as well known biochemically; it is resistant to proteolytic enzymes, but more recent work suggests that it is also protein in nature. The M and T antigens are independent and may occur in various combinations. Thus, types 10 and 12 contain the same M antigen but different T antigens, while types 15, 17, 19, 23, and 30 contain very closely related T antigens but distinct M antigens. In addition, strains are found which lack T antigen, and still others lack, or apparently lack, M antigen. An additional antigen, designated the "R"

antigen and similar to M antigen except that it is resistant to tryptic digestion and antiserums to it are not protective, was found first in type 28. Subsequently, it has been found, through use of the indirect bactericidal test,⁵⁵ in types 2, 3, and 48.⁴⁶, ⁴⁷

The nature and distribution of these antigens within the β -hemolytic streptococci of Group A, *i.e.*, Str. pyogenes, are shown in the accompanying tables.

While the separation of the streptococci of Group A is a complex matter, streptococcus typing has been rather generally applied, in part because it is of importance in the interrelationships, possibly phylogenetic, of the streptococci, and in part because it is of great value in epidemiological studies. 66 Many workers feel that slide agglutination is not completely satisfactory and favor the precipitin reaction; a method of carrying out the precipitin test in capillary tubes which is reliable and conserves serum has been developed.

Content of M antigen varies and is apparently related to the virulence of the strain, while T antigen usually remains constant within a given strain. Since type is determined largely by the M antigen, a strain which has small amounts of this antigen, or has temporarily lost it, may be difficult to type, though type may at times be inferred from the T antigen present. It may be progressively lost during infection coincident with increasing susceptibility to antibody activity,79 or more than one M antigen may occur as in the type 14 strains, found¹¹⁰ to contain a new M antigen, designated 51, and the mixed type as type 14/51; similar multiple type specificity occurs among the pneumococci (Chap. Eighteen). Rarely, the group-specific C polysaccharide may be apparently lost and replaced by a new poly-

Antigens of Streptococcus pyogenes*

saccharide, V polysaccharide, differing in that the ratios of rhamnose to acetylglucosamine are shifted from 1.6 for the C polysaccharide to 4.5. The change may be a superficial one chemically.⁵⁷

Streptococci falling into other Lancefield groups on the basis of the specificity of the "C" substance are also divisible into types. In Group B, the bovine mastitis streptococci, four main types and a number of subtypes have been differentiated. In this group there is but a single type-specific antigen, and it is polysaccharide in nature.

Distribution of Type-specific Antigens of Streptococcus pyogenes*

Group C contains, in addition to the three Griffith types noted above, 10 additional types, five in strains of human origin, and five in strains from horses, making 13 in all. Here also there is but a single type-specific antigen, and it is protein in nature. Types have been differentiated in several of the other groups, such as Group D, 18 on the basis of a single type-specific antigen, polysaccharide in nature.

While the antigenic structure just discussed is largely that of the β -hemolytic streptococci, β -hemolysis is not invariably associated with the immunological character of these groups, and it has been found that certain of the enterococci, for example, contain these antigens. By and large, however, this antigenic structure does not extend far beyond the β -hemolytic group, and, as indicated above, immunological methods have not been useful in other than this group.

Physiological differentiation. There is some correlation between the immunological groups of the hemolytic streptococci and their physiological characteristics. Group A shows a reasonable degree of biochemical homogeneity. All produce β -hemolysis on blood agar and form soluble hemolysins, do not hydrolyze sodium hippurate, ferment trehalose but not sorbitol, do not reduce methylene blue, and seldom grow in 40 per cent bile agar. Group B is also more or less homogeneous differing from Group A in that sodium hippurate is

hydrolyzed and growth occurs in 40 per cent bile agar, but resembling that group with respect to methylene blue reduction and trehalose and sorbitol fermentations.

The streptococci of Group C are considerably more diverse and resemble Group A in that sodium hippurate is not hydrolyzed. Within the group there is some correlation between habitat and physiological character. Thus the strains isolated from strangles in horses are sorbitol-, trehaloseand lactose-negative, while strains that are pathogenic for man generally ferment sorbitol but not trehalose.

Physiological characteristics have been used exclusively in the Bergey (1957) classification of the streptococci and the species differentiated on that basis are indicated in the accompanying abridged key.

Most of these species are generally accepted, and it will be clear from the foregoing discussion that all members of Group

I. Facultative anaerobes

A are known as Str. pyogenes, the immunological varieties within the group being types of Str. pyogenes. Two species are included in Group C. The name Str. zooepidemicus is a relatively new one introduced in the Bergey (1948) classification; it does not replace another name, but rather gives species status to the animal pathogens of this group formerly casually known as "animal pyogenes" which rarely occur in man. The other species, Str. equisimilis, includes those streptococci formerly known as "human C" and which are uncommon in lower animals. Of the β -hemolytic streptococci found in man, 95 per cent or more are Group A and therefore Str. pyogenes, and the remainder, Group C, are Str. equisimilis, differentiation being made by the precipitin test, using group-specific antiserums. Of the green streptococci found in man, the most common are Str. faecalis of the enterococcus group and Str. mitis and Str. salivarius of the viridans group. So far as the etiology of streptococcal infections in man is concerned this differentiation 109 and that of Str. faecalis and Str. faecium are unimportant. The identification of streptococci which do not fall into the Lancefield groups is a matter of detailed biochemical study.

Pathogenicity for animals. As indicated above, certain of the streptococci are responsible for specific diseases of domestic animals. Str. equi is the cause of strangles in horses, a suppurative infection of the upper respiratory tract that is characterized by abscess formation in the throat and submaxillary region. This species is apparently not pathogenic for man. Other strains of Group C infect horses, causing respiratory catarrh and suppurative lesions in various parts of the body.

The most common cause of streptococcal mastitis in the cow is *Str. agalactiae*, which produces a chronic infection that is, as a rule, more common in older cattle. The infection is probably spread by the hands of the milker for the most part. Mastitis may also be caused by *Str. pyogenes* and may result in the spread of milkborne streptococcal infection of man; it is probable that the source of infection is man and that *Str. pyogenes* does not occur naturally in the cow.

Various other suppurative conditions, often involving infection of lymphatic tissue in animals such as the dog and sheep, are of streptococcal etiology. Some are Group A streptococcal infections, as in the

case of epizootics which have been observed to occur in wild rodents⁴ and laboratory mice,³² but usually are β -hemolytic streptococci of groups other than Group A; there are a few reports of spontaneous infections of lower animals with green streptococci.

Str. pyogenes is pathogenic for most laboratory animals, including the mouse, guinea pig, and rabbit, but different strains vary widely in virulence for different animals; virulence may, of course, be enhanced by animal passage. Intravenous inoculation of virulent strains results in fatal septicemia; suppurative peritontis developing into septicemia follows intraperitoneal inoculation, and subcutaneous inoculation produces an abscess from which the infection may or may not spread. Pneumonia may be produced in rats by the intrabronchial inoculation of the bacteria suspended in mucin. Str. agalactiae is of low virulence for experimental animals, and Str. equi is highly virulent only for the mouse. The green streptococci are also relatively avirulent for laboratory animals but may produce local infections on intravenous inoculation following injury; such techniques have been used to produce experimental arthritis lesions in the rabbit.

Pathogenicity for man. 56 The streptococci are responsible for a wide variety of diseases of man, perhaps a greater variety than any other kind of bacteria, and, in addition to being the primary cause of disease, they have a marked tendency to occur in mixed and secondary infections with other pathogenic bacteria. In general, the streptococcal infections are characterized by suppurative lesions and very often manifestations of toxemia, the latter taking the form of the so-called nonsuppurative complications of the infection and including fever, arthritis, carditis, and nephritis. They vary in the extent to which the body is involved, from local infections such as abscesses of the various tissues, including mucous membranes, joints, and serous membranes, infection of the muscle or cellulitis which simulate gaseous gangrene, suppurative processes in all kinds of wounds, to those generalizing to pyemia or septicemia. Some streptococcal infections have no distinctive clinical manifestations; thus an abscess caused by streptococci is not distinguishable from one of staphylococcal etiology. Others, however, such as erysipelas, streptococcal sore throat, scarlet fever, and the like, have to a greater or lesser degree some distinctive clinical character.

There are appreciable differences in the character of streptococcal infection in the child and in the adult, and the lower age groups are relatively the more susceptible. In the infant the infection tends to be a prolonged, low-grade infection with frequent suppurative complications, but rheumatic fever and nephritis seldom follow. In older children and adults the infection tends to be acute and self-limited and with nonsuppurative complications.

The β -hemolytic streptococci are by far the most virulent and, as indicated above, the great majority of those infecting man are of Group A, Str. pyogenes. The small proportion of infections with Group C streptococci are not distinguishable from those of Group A except by isolation and immunological typing of the etiological agent. Human infection with Group B streptococci is described from time to time^{45, 53} but is

The pathogenicity of these bacteria is accounted for to a considerable degree by the soluble toxic substances they produce.² The most clear-cut example is that of the relation of the erythrogenic toxin to scarlet fever, but it is probable that other toxic substances also play a part in the development of the pathological condition.

The association of fibrinolysin with virulence seems definite, so much so that this activity has been termed invasin by some workers.

The role of the streptolysins in the development of the pathology of streptococcal infections is not too clear. Both streptolysin S and streptolysin O are toxic for experimental animals, the former causing death through intravascular hemolysis. The mechanism of the lethal action of streptolysin O is not known; it may possibly be related to the cardiotoxic action of this substance described by Bernheimer. There is some reason to believe that the destructive effect of streptococcal filtrates on polymorphonuclear leucocytes, attributed to the presence of a leucocidin, is closely related to or identical with streptolysin O, but in any case this activity may make up a significant part of the invasive and pathogenic properties of the streptococci. The presence of the type-specific M antigen is associated with virulence, and antibody to it is protective while antibody to the type-specific T antigen is not. Hyaluronic acid capsules seem to be at best a minor component of virulence among Group A streptococci but appear considerably more important in this respect in Group C.

In general, then, while knowledge of the mechanisms of the pathogenic action of the β -hemolytic streptococci is far from complete, there is a considerable body of evidence which indicates that the production of disease is due at least in part to the action of the several toxic substances formed by these bacteria. As indicated earlier, strains of streptococci differ with respect to the kinds and amounts of such substances that they produce, and this variability accounts in part for the differences in disease they may produce. Thus, both strains which produce erythrogenic toxin and those which do not may produce septic sore throat, but only the former can produce scarlet fever also. These are not the only factors, of course, and the route of infection and immunity of the host are significant also; for example, wound infection and streptococcal sore throat involve different routes of infection, and an erythrogenic toxin-producing strain can produce sore throat but not scarlet fever in the immune.

Streptococci other than the β -hemolytic varieties are much less virulent.²¹ The α hemolytic forms constitute a portion of the normal bacterial flora of the mouth, upper respiratory tract, and intestinal tract. It is probable that they seldom initiate infection of the healthy tissues, but when natural resistance has been reduced they may be able to set up low-grade, essentially localized, infections such as focal abscesses in the teeth and gums.78 They are the most common cause of subacute bacterial endocarditis but, while the condition is a serious one, the infection shows little or no tendency to spread throughout the body in spite of the frequent presence of the streptococci in the blood stream.

Pneumonias of α -streptococcal etiology occur from time to time. ¹⁹ The disease tends to assume a chronic relapsing condition, with pleuritis and lung infiltration, and a tendency to bilateral involvement. It resembles viral pneumonias superficially, but differs in that there is a marked leucocytosis. A few instances of α -hemolytic streptococcal meningitis have been reported, ³⁸ but are rare.

Streptococcus MG. The nonhemolytic, or anhemolytic, streptococci are largely saprophytic forms, often found in milk and dairy products, and have been associated with disease only in rare cases of subacute bacterial endocarditis. They are occasionally isolated in atypical pneumonias, which are most often of varied viral etiology, but apparently are not causally related to the disease. One such strain, designated streptococcus MG, has been isolated from the sputum in a series of cases of primary atypical pneumonia, and proved to be biochemically and antigenically homogeneous.61 About half the cases of such disease develop specific agglutinins for this strain of streptococcus, and these are known as MG agglutinins. This antibody response is distinct from the cold hemagglutinin that also occurs in primary atypical pneumonia, and the two kinds of antibody have empirical diagnostic utility although so far as is known they have no bearing on the Mycoplasma etiology of this disease (Chap. Twenty-seven).

Epidemiology of streptococcal disease. The primary source of pathogenic streptococci is the human being who carries these bacteria in the upper respiratory tract. The infection may not be associated with symptoms, and carrier rates of 4 to 25 per cent to as much as 40 to 60 per cent in schoolchildren, with cumulative percentages as high as 75 to 90 per cent,68 have been reported. It is estimated that overt streptococcal infections occur in all individuals from time to time, at intervals of perhaps two to five years, but the incidence of subclinical infections is not known other than in restricted groups. Those with overt symptoms of disease such as tonsillitis, pharyngitis, sinusitis, and scarlet fever are prolific sources of infection. While streptococci may be present in the saliva as well as in the throat, and discharged by sneezing, coughing, and contamination of the hands, the nasal carrier is by far the most dangerous and contributes very large numbers of streptococci to his environment. Not only is the carrier the source of infection, but the streptococcal disease may take a variety of clinical forms. In an epidemic of scarlet fever, for example, the cases of pharyngitis and rhinitis are as important as those of frank scarlet fever, i.e., those showing a rash, in the spread of the infection; in fact it is customary to record the incidence of scarlatinal rash in a given epidemic rather

than differentiate scarlet fever from other streptococcal infections of the upper respiratory tract.

The transmission of streptococci from the infected person to the susceptible individual is in part a matter of direct contact and in part one of contamination of the environment.51,65 Direct contact include inhalation of infective droplets expelled from the nose and mouth, hand-tohand contact, etc., while contamination of the air with droplets too small to settle, and through air and droplet infection the contamination of dust. Direct contact with the hands no doubt accounts for wound infection, puerperal fever, infection of the udder with Str. pyogenes to produce mastitis and milkborne streptococcal disease, and possibly infection of the upper respiratory tract to a certain extent. Most upper respiratory tract infection is airborne, 29, 30 either directly or through the agency of resuspended infected dust. The importance of the last is very great, and dust suppression measures such as oiling of blankets in hospital wards sharply reduce the incidence of streptococcal infection.

Although some streptococcal diseases are reportable, the incidence of streptococcal infection can only be estimated; probably about seven million infections occur each year in this country.

Immunity to streptococcal infection. Antibodies to the streptococcus cell substance and to the antigenic soluble products of these organisms are formed following immunization or infection. In the case of Str. pyogenes, the former include the type-specific M and T antigens as well as the groupspecific C substance. In the latter group are the erythrogenic toxin, streptolysins S and O, hyaluronidase, and fibrinolysin. Antibody formation has no diagnostic utility in acute streptococcal infections, in part because there is not sufficient time for antibody formation during the course of the disease, at least in its early stages, and in part because isolation and, if desirable, typing of the infecting microorganism are relatively simple. Antibody titration is useful for diagnosis in retrospect, i.e., in associating streptococci with diseases such as rheumatic fever and arthritis, and for the determination of susceptibility to scarlet fever on the basis of antibody to the erythrogenic toxin.

The immunized animal responds to the

cell antigens of streptococci with the production of precipitating and agglutinating antibody, and the use of such antiserums makes possible immunological grouping and typing. The immune response of man to these antigens during the course of infection appears more often to take the form of the development of a hypersensitivity, especially in the rheumatic diseases, and the immunological response may be measured by intradermal inoculation of soluble streptococcal antigens. More often serum is titrated for antibody to streptolysin or fibrinolysin by in vitro methods. The antistreptolysin O, or ASO, titration is commonly carried out, but may require caution in interpretation in that human serum may in some conditions, especially hepatitis, have an inhibitory activity associated with lipid content and unrelated to antibody.

Quite aside from the question of the etiology of such diseases, the occurrence of such antibodies in the human population is not uncommon, as might well be expected from the frequency with which streptococcal infection occurs. It is sometimes stated that 70 to 80 per cent of persons having streptococcal disease show significant increases in antibody titer to streptolysin O, streptokinase, and hyaluronidase. The erythrogenic toxin also stimulates the formation of specific antitoxin, following both clinical scarlet fever and immunization with the toxin, and, like diphtheria antitoxin, the incidence of its occurrence rises with age, indicating that immunization occurs without the intervention of clinical scarlet fever. Intradermal inoculation of erythrogenic toxin gives a skin test, analogous to the Schick test in diphtheria, which allows the estimation of the immunity of the individual to the toxin. Antibody to the erythrogenic toxin cannot be titrated by in vitro methods, or to a satisfactory degree in experimental animals because of their relative lack of susceptibility to its action.

Differentiation must be made between an immune response in the technical sense of antibody formation and an effective immunity which prevents and/or modifies the infection or disease. The only immunity to streptococcal disease that is unquestionably effective is immunity to the erythrogenic toxin, which is reflected as immunity to the clinical disease scarlet fever. In general, immunity to streptococcal infections is of a low order and in any case transient. That some degree of effective immunity to a given type of streptococcus may be produced is indicated by recovery from and elimination of the infection in naturally occurring disease, and there is also some experimental evidence of the existence of an effective immunity. It has been found, 106 for instance, that a nasopharyngeal carrier state induced in monkeys resulted in an increase in antistreptolysin O titer of the serum and a resistance to reimplantation with the same strain that persisted for some months.

Unfortunately such immunity appears to be type-specific and, as pointed out earlier, associated with antibody to the M antigen. and there is only a small degree of crossimmunity. Since the M antigen appears to be located primarily, or even exclusively, in the cell wall, it has been inferred by some that its association with virulence is analogous to that of the pneumococcus capsule in that it interferes with phagocytosis. It would follow, then, that the effective immune response is opsonic, and studies utilizing the phagocytic index and similar criteria show a correlation between effective immunity and this humoral antibody. With the multiplicity of streptococcus types in the species Str. pyogenes, an effective immunity to streptococcus infection appears to be a somewhat impractical end.

Chemotherapy. The chemotherapeutic efficacy of the sulfonamides was first observed in experimental infections with Str. pyogenes. These compounds continue to be effective chemotherapeutic agents in infections with the streptococci but have been displaced to a considerable extent by the antibiotics, especially penicillin. Penicillin has been of special interest in the mass prophylaxis of epidemic streptococcal infection and in reducing the carrier rate in military populations.84 The hemolytic streptococci are more susceptible to these agents in vitro than are the staphylococci. The susceptibility of the green streptococci to the antibiotics is, in general, approximately the same as that of the staphylococci, but is subject to such wide variation from strain to strain that antibiotic sensitivity tests are practically mandatory. Bacterial endocarditis of α -hemolytic streptococcal etiology is the most important of the diseases produced by these streptococci, and the susceptibility of the causative strain is usually such that massive therapy is effective.⁵⁴

The relative efficacy of chemotherapy is dependent upon the kind of disease produced by the streptococci. For example, puerperal sepsis, streptococcal sore throat, pneumonia. and ervsipelas generally respond well to chemotherapy, but the rash of scarlet fever is not affected, nor is the therapy of acute rheumatic fever satisfactory. Chemotherapy does eliminate the focus of infection in scarlet fever and decreases the incidence of suppurative complications. The failure of rheumatic fever to respond to antimicrobial therapy is due to the lag of symptoms behind the actual infection and probable role of hypersensitivity (see below). Prevention of recurrent streptococcal infection in affected individuals is highly significant, and repository penicillin is an effective prophylactic agent.94

As in certain other infections, the prompt use of effective chemotherapeutic agents, especially penicillin in streptococcal infections, inhibits the immune response as compared to the untreated infection, probably as a consequence of reduction in the total

antigenic stimulus.

Bacteriological diagnosis of streptococcal infection. 111 Isolation of streptotococci from specimens of pathological material is ordinarily not difficult. An enriched medium is required, and blood agar is the medium of choice, for both α -hemolysis and β -hemolysis are apparent. Overgrowth by Proteus in cultures of some kinds of specimens may be prevented by including 0.02 per cent sodium azide in the medium. Most specimens, such as throat swabs and pus, may be streaked directly on blood agar, but enrichment culture, as in veal infusion broth containing 0.1 per cent dextrose and 0.1 per cent phosphate buffer, should be made with blood taken for culture, incubated for 24 hours, and then streaked on blood agar. If there is reason to believe that the specimen contains sulfa drug, its bacteriostatic effect may be neutralized by including 5 mg. per 100 ml. of p-aminobenzoic acid in the med-

The colonial morphology is typical in the case of β -hemolytic streptococci, and the characteristic chains of cocci may be found in Gram-stained smears. Green streptococci from sputum and similar specimens must be differentiated from pneumococci by inulin fermentation and bile solubility. The hemolytic streptococci may be typed by agglutination with type-specific antiserums and by

the precipitin test. For the latter the sedimented bacteria from a 250 ml. broth culture are suspended in 10 ml. of M/10 HCl in saline, boiled for 10 minutes, cooled in running water, and the insoluble material spun out to leave a clear supernatant to be used as the antigen. Considerable economy of reagents may be effected by setting up the precipitin test as a ring test in capillary pipettes; the precipitate at the serum-antigen interface may be observed with a hand lens.

There has been some interest in the use of the fluorescent antibody technique for the identification of Group A streptococci,⁴¹ but the method has been considered⁷¹ of limited value as applied to direct throat smears.

STREPTOCOCCAL INFECTION OF THE SKIN AND SUBCUTANEOUS TISSUES

Erysipelas. The ability of streptococci to infect the skin and adjacent tissues is well illustrated in erysipelas, an inflammatory disease of the skin caused by Str. pyogenes. There is some evidence that an attack of the disease is preceded by streptococcal infection of the throat or elsewhere in the upper respiratory tract, and it has been found that some individuals at least have the same immunological type of streptococcus in the throat as in the skin lesions. It is not clear whether the skin is directly invaded. or whether the microorganisms reach the area by some internal route, but the latter is only suggested and by no means established. The etiological relationship of Str. pyogenes to the disease is indicated by its presence, frequently in enormous numbers, in the lesions, the production of erysipelaslike disease in rabbits by the inoculation of streptococci, and inoculation experiments in carcinomatous patients which have demonstrated that pure cultures of streptococci can provoke the erysipelatous process. It is possible that hypersensitivity may contribute to the pathogenesis of the disease.3

Streptococci are not present in the central portion of the inflamed area, but are found on its periphery, and can be isolated most readily by excision of portions of the tissue, other methods rarely succeeding. In the skin they occur chiefly in the lymph

spaces, which are often packed with them, and may be recovered by skin puncture as far as 3 cm. beyond the advancing edge of the lesion where there is no gross evidence of inflammation. The hypothesis that the inflammatory reaction is due in part at least to the erythrogenic toxin has been an attractive one, but it seems definitely established that there is no relation; immunization with erythrogenic toxin, for instance, in no way prevents or reduces the inflammatory reaction in erysipelas.

This disease and especially experimental erysipelas in the rabbit, has been of considerable interest in connection with problems of local and tissue immunity. It is well established that one attack of the disease confers no protection against subsequent attacks, and in the opinion of many, some persons have a predisposition to the disease, suffering repeated attacks throughout life and even in the same areas. In the experimental disease in the rabbit, however, a number of workers have reported that successive intradermal inoculations bring about an increased resistance to subsequent inoculation in that area, and that with continued immunization the area increases slowly in size. The immunity is not highly specific, and inoculation of sterile broth also results in some increase in resistance to infection. Consistent with this, immune serum, when mixed with streptococci and inoculated intradermally, seems to have some protective effect. Serum therapy of the human disease, however, appears to produce only a possible mildly favorable effect upon the immediate attack but none upon recurrences and complications such as abscess formation.

Wound infection. 67 The green streptococci seldom occur in infections of wounds, but Str. pyogenes produces a suppurative infection when present, especially late. This organism is not normally present on the skin, and, in fact, normal skin has a bactericidal effect upon it. The relative rarity of infection of wounds by these bacteria is consistent with this, and streptococcal infection in most instances is a result of subsequent contamination by direct contact rather than of a primary infection. Str. pyogenes may occur alone or in mixed infections with other pyogenic bacteria such as staphylococci.

Cellulitis.⁵² Traumatic invasion of the skin and subcutaneous tissues may not remain localized but may develop into an

acute, spreading infection of the subcutaneous tissue with invasion of the muscle giving rise to gangrenous myositis. The infection to the subcutaneous tissues may show little or no evidence of localization and is characterized by the formation of a seropurulent exudate. It tends to spread rapidly via the lymphatic tissues and generalize into septicemia. This kind of streptococcal infection has been termed cellulitis, and may result from *Str. pyogenes* alone or, in the development of the gangrenous process, more often in mixed infection with anaerobic streptococci. This kind of wound infection was found in World War II.

STREPTOCOCCAL INFECTION OF THE UPPER RESPIRATORY TRACT¹⁰

As indicated earlier, the β -hemolytic streptococci occur most commonly as parasites and pathogens of the upper respiratory tract. By far the largest proportion of human disease caused by Str. pyogenes results from infection of the upper respiratory tract and adjacent areas, symptoms arising not only from the acute infectious process, but also in connection with its complications. The clinical character of the disease is determined by the relative prominence of the various results of the infection and, while seemingly different, is fundamentally the same. Thus streptococcal pharyngitis or septic sore throat becomes scarlet fever when the infecting strain of Str. pyogenes produces erythrogenic toxin, the infection commonly extends into the tonsils or may be localized primarily there to give clinical tonsillitis; it may extend into the sinuses or middle ear to produce streptococcal sinusitis and otitis media respectively, and by extension into the lungs result in bronchopneumonia of streptococcal etiology. Further, late nonsuppurative complications of streptococcal infection include carditis, nephritis, and arthritis. While separation of B-hemolytic streptococcal infection into various clinical entities has some practical value, the basic infectious process is essentially the same.

The green streptococci are also inhabitants of the upper respiratory tract, as pointed out earlier, and are so constantly present and of such restricted pathogenicity that they are a part of the normal bacterial

flora. Infection of the teeth and gums undoubtedly stems from this area, and it is likely that the bacteria entering the blood stream to produce local infections elsewhere in the body originated in the upper respiratory tract. They are occasionally found in bronchopneumonia. 92, 97

Streptococcal sore throat (septic sore throat). The β -hemolytic streptococci are responsible for an acute infection of the throat commonly known as septic or streptococcal sore throat. Epidemics of this disease appeared in the United States and in England during the first decade of the present century. The immediate symptoms in these and subsequent epidemics have been strikingly similar and include an intense local hyperemia, with or without a gravish exudate, enlargement of the cervical lymph nodes, and usually fever. Extension of the infection into the lungs may occur with resulting streptococcal pneumonia³⁵ which may terminate in fatal septicemia, and peritonitis has been a cause of death also. The disease, usually in a relatively mild form, is a common one.

The sequelae of streptococcal sore throat include those resulting from the extension of the infection into adjacent areas such as the sinuses and middle ear, and purulent, semichronic infections often develop. Streptococci also frequently persist in tonsillar crypts in a chronic type of infection which may flare up periodically in an acute form. Streptococcal tonsillitis, sinusitis, and otitis media are, then, a part of the pathology of hemolytic streptococcal infection of the throat. In addition to such extensions, the effects of toxemia on other parts of the body are evident as carditis, nephritis, and arthritic involvement of the joints. As in the case of scarlatinal rash noted earlier, the character of an epidemic is often recorded as percentage incidence of these various sequelae.

The distinctive clinical character and epidemic spread of the disease led earlier workers to believe that it was caused by a particular kind of streptococcus to which the name Str. epidemicus was given. It is now established that various immunological types of Str. pyogenes are, for the most part, responsible for the disease, and a small portion of the cases are infections with streptococci of Group C, now grouped as Str. equisimilis. On the other hand, there is reason to believe that so-called "epidemic

strains," of high virulence and infectivity, of streptococci as well as other bacteria are often associated with epidemic disease.

It is probable that the infection is largely droplet and airborne, including dust, but there is no doubt that in many instances direct contact is of considerable significance. It may also be transmitted through food and milk and streptococcal infection is often milkborne. In the past it has been assumed that the contamination was direct from man, but evidence has accumulated which indicates that mastitis of *Str. pyogenes* etiology may constitute the immediate source of infection of the milk.

SCARLET FEVER

Scarlet fever is a clinical entity because of the rash resulting from the action of the erythrogenic toxin; otherwise it does not differ significantly from other streptococcal infection of the upper respiratory tract, and its sequelae are essentially the same.

While scarlet fever has declined in prevalence and severity since the turn of the century, following a period of high prevalence during the nineteenth century, it has behaved differently in different parts of the world in the last two or three decades. It increased in continental Europe after World War II and remained at a high prevalence, while in England and Wales it continued at a fairly constant level, and has declined sharply in the same period in the United States and Canada.⁶⁴

The relationship of β -hemolytic streptococci to the disease was demonstrated by Dick and Dick in 1923 by the reproduction of typical scarlet fever in human volunteers, by the inoculation of pure cultures, and by the demonstration of the existence of the erythrogenic toxin. A conclusive demonstration of the etiological relation was required because of the contrast between the relatively lasting immunity to scarlet fever following recovery from an attack of the disease and the transient immunity to other streptococcal infections. It has been held by the Dicks and others, largely on the basis of early agglutination studies, that the scarlet fever streptococci constitute a homogeneous group of \(\beta\)-hemolytic streptococci which should be designated Str. scarlatinge. While the streptococci found in scarlet fever are all members of Group A, i.e., Str. pyogenes,

the ability to form erythrogenic toxin is not confined to any particular type within this group, though some types occur more frequently than others, and it cannot be said that the scarlet fever streptococci are immunologically homogeneous. Neither are they biochemically homogeneous, and in the Dicks' early experiments the mannitol fermentation was variable in scarlet fever-producing strains. It appears, then, that the scarlet fever streptococci are strains of *Str. pyogenes* that have in common the ability to form erythrogenic toxin, but such strains are found in conditions other than scarlet fever, such as erysipelas.

The erythrogenic toxin.¹⁷ It is generally agreed that the scarlatinal toxin is protein in nature, but some workers have reported that it is heat-stable and others that it is heat-labile. It has been found, however, that heat-lability is determined by methods of preparation. The purest preparations, prepared by ammonium sulfate and cold ethanol fractionation, contain 11,250 Lf/mg. N or 2100 Lf/mg. protein. Four components have been demonstrated by electrophoresis; the toxicity was associated with the slowest, and on separation this contained 108 STD per mg. Whatever its nature, it is necessarily assayed by skin test and its potency is measured in skin test doses (STD), the smallest amount that will produce the characteristic erythematous response. It is antigenic and is flocculated by antitoxic serums but in multiple zones, and the flocculation titration must be carefully controlled.36

Scarlet fever antitoxin. The therapeutic use of antistreptococcus serums was investigated by Moser in 1902 with encouraging results, and similar observations were reported by Dochez and others in 1924. The Dicks prepared specific antitoxic serums by immunizing horses with sterile culture filtrates. The results of the therapeutic use of the Dick antitoxin are favorable on the whole, though the mildness of the prevalent type of scarlet fever makes it difficult to secure any large body of statistics as cogent as those recorded in diphtheria. In individual cases, however, the administration of antitoxin decreases the duration of the rash, changes the character and extent of desquamation, and reduces the number of complications, and there is general agreement as to the efficacy of antitoxic serum properly prepared and administered early. Some clinicians would restrict the use of scarlet fever antitoxin to cases of severe or toxemic type. A unit of antitoxin is defined as that amount which will neutralize 50 skin test doses of toxin.⁷⁰

Immunity to scarlet fever is, in a sense, a clinical immunity in that it is largely an immunity to the erythrogenic toxin rather than to the streptococcus. It may be demonstrated by the Dick test, a skin test analogous to the Schick test in diphtheria; i.e., the local erythema is due to the action of the toxin and is absent in the presence of antitoxin, either of exogenous origin or present in the immune individual. The Dick test may be used, then, to ascertain whether or not an individual is immune to scarlet fever or. more precisely, whether circulating antitoxin is present. In this connection it is of interest that Schultz and Charlton earlier observed that when a scarlet fever patient with a bright-red rash is injected with 1 ml. of convalescent serum, after about six hours the rash begins to fade and soon disappears completely. The significance of this phenomenon, the Schultz-Charlton blanching phenomenon, was not recognized at the time.

Scarlet fever, like the other hemolytic streptococcal infections, may be effectively treated with penicillin, to reduce the period of illness and the number of complications. Early chemotherapy seems to interfere with the development of the immune response, as indicated by the antistreptolysin titers, and the relapse rate is not reduced.⁸⁵

Prophylactic inoculation. The It is not generally known that following Jenner's work on smallpox vaccination attempts were made to immunize against scarlet fever by a similar process of inoculation. Preventive inoculation with killed streptococcus cultures was practiced by Russian bacteriologists as early as 1906. Mild symptoms were produced similar to those observed in scarlet fever. A single injection did not suffice to produce immunity, two or three inoculations being necessary. It was believed that a considerable degree of immunity was obtained by this procedure.

The discovery of the scarlet fever toxin offered an opportunity for protective immunization similar to that successfully utilized to diphtheria. Toxins with a potency of at least 40,000 STD per cubic centimeter are preferable, and appropriate dilutions are injected at intervals of one week. Five injections are recommended, starting with 500 STD and gradually rising to about

100,000 STD. Immunization of susceptibles (Dick-positives) in this manner produces 98 per cent or more Dick negatives. The injections are sometimes accompanied by the development of a scarlatiniform rash and other symptoms of mild scarlet fever. In consequence, the use of toxin detoxified by treatment with formalin has been advocated by some workers. It is to be emphasized that immunity to scarlet fever is an immunity to clinical scarlet fever, not to the streptococcal infection, and from the epidemiological point of view both Dick-negative and Dick-positive individuals must be considered as having scarlatinal infections. the only difference being the clinical one dependent upon the development of a rash.

As in the case of diphtheria, immunity to scarlet fever may be acquired by inapparent infection. The frequency of positive Dick tests is low in newborn children (indicating a passive immunity of maternal origin), then rises to a maximum in the age groups one to five years, and thereafter falls off gradually until in persons over 30 it is relatively low, possibly 15 per cent.

RHEUMATIC FEVER 42, 91, 99

As indicated earlier, not uncommon sequelae of β -hemolytic streptococcal infection include carditis and arthritic involvement of the joints. These are emphasized and assume a major role in the pathology and symptomatology of the post-streptococcal nonsuppurative inflammatory disease known as rheumatic fever, acute rheumatism, or rheumatic heart disease and occurs as a sequel to streptococcal infection in about 3 per cent of cases in closed populations, but at a lower rate, 0.1 to 0.3 per cent, in the general population.

The essential lesion of rheumatic fever is carditis, which may or may not be accompanied by pyrexia and arthritis. The carditis includes the connective tissue degeneration characteristic of the damaged heart valves, and specific inflammatory myocardial lesions characterized histologically by nodular collections of cells described by Aschoff and known as Aschoff nodules. Rheumatic fever is the third most common infectious disease in this country, exceeded only by tuberculosis and syphilis.

The connection between β -hemolytic streptococcal infection and rheumatic fever

is very close, and there is good reason to believe, though as yet not complete and unequivocal proof, that the relationship is etiological. The epidemiological association of streptococcal infections such as tonsillitis, puerperal fever, scarlet fever, and the like, with rheumatic disease has long been recognized. It is reinforced by evidence of an immunological response, such as rising ASO titers, to streptococcal infection almost invariably associated with rheumatism; an ASO titer of 200 or more is generally considered to be indicative of recent infection.

Rheumatic carditis occurs in some individuals; the lesion is a nonpurulent inflammation of the valve cusps and rings and formation of verrucae on the margins which are eventually replaced with scar tissue. Rheumatic myocarditis commonly occurs also, and is characterized histologically by the perivascular granulomata known as Aschoff bodies or nodules. Dome observations suggest that there is an individual tendency to valvular involvement, and when this does not occur in the first attack, it is less likely to in subsequent attacks.

The onset of the disease does not necessarily coincide with acute streptococcal disease and only rarely has it been possible to culture β -hemolytic streptococci from the blood. Largely through the work of Coburn, beginning in 1931, these discrepancies have been reconciled, and the etiological relationships of the β -hemolytic streptococci clearly indicated.

Coburn differentiates three stages in the disease: first, an acute streptococcal infection of the nasopharynx; second, a period of quiescence during which streptococci remain the the throat; and third, the stage in which electrocardiographic changes are apparent and the symptoms of acute rheumatic fever appear. During the third stage streptococci may or may not be demonstrable, and the symptom complex appears to be a consequence of a developed hypersensitivity to the streptococcal antigens (see below). The time which elapses between the first and third stages varies from one to five weeks in patients in whom it has been studied. A practically significant point is that, since clinical rheumatic fever is not a direct result of streptococcal activity, chemotherapy is not effective.

Subsequent attacks occur on reinfection with streptococci, or occasionally following

nonspecific febrile events, and control of the disease in the individual consists in chemoprophylaxis. Repository penicillin, e.g., benzathine penicillin G, and sulfonamides are satisfactory, but the broadspectrum antibiotics are not. The time over which prophylaxis must be continued is uncertain, but some evidence suggests that recurrences drop sharply after age 18.38

The mechanism by which streptococci produce rheumatic fever is far from clear. The antibody response to the initial infection is delayed in that peak titers of antistreptolysin O, complement-fixing antibody, and group- and type-specific precipitins occur in the third stage of the disease rather than earlier, while antistreptolysin S declines in the third stage, particularly in those having recrudescences. There is reason to believe that hypersensitivity exists to the streptococcus or its products; for instance, joint pains are often produced in rheumatic patients by the inoculation of sterile streptococcus culture filtrates. It appears that an immune response is basic to these consequences of streptococcal infection, but whether this is a conventional antibody response or a hypersensitivity, or both, is not clear. As regards the former, there is reason to suspect that an auto-immune response occurs³⁹ which would put rheumatic fever and its sequelae with the collagen diseases; there is, for example, evidence of bound y-globulin in cardiac tissue. A sensitization may be one to streptococcal antigen, and if so it is an antigenicity widely distributed over types of Str. pyogenes, or to a complex of streptococcal and tissue antigenicities.40

It is quite likely also that the role of the host is of considerable importance. There is evidence of hereditary susceptibility to rheumatic fever, 115 and some indication of a constitutional predisposition to rheumatic fever; the disease occurs more commonly in hyperthyroid persons, there is some evidence suggesting that lipid metabolism may be involved, and it occurs more commonly in the 5- to 15-year age group than in older persons.

It has been of some interest that many of the lesions characteristic of rheumatic fever may be produced in the rabbit⁶² by inoculation of β -hemolytic streptococci, and with cell-free sonic lysates of streptococci in the mouse.¹³ These include nonsuppurative

myocarditis (without, however, the typical Aschoff nodule), endocarditis, and arthritis ranging from mild to severe with extensive changes in the bone. While it may be argued that such pathology is not identical in all respects with that of rheumatic fever in man, the fact that such lesions can be produced experimentally by the inoculation of streptococci or their products may be regarded as strong evidence in support of the assumption that these bacteria may be etiologically related to human rheumatic fever.

In general, then, it seems quite clear that there is a very close, probably etiological, relation between *Str. pyogenes* and rheumatic fever, but the pathogenesis of the disease is far from clear.

ACUTE GLOMERULONEPHRITIS

An association of acute hemorrhagic glomerulonephritis with streptococcal infection has been known for many years, beginning, in fact, with Bright's description of the condition in association with scarlet fever as early as 1836. A causal relation between streptococcal infection and this disease appears to be definitely indicated by application of typing methods to give a high correlation between this kind of nephritis and certain types of streptococci.^{72, 108, 113}

In contrast to rheumatic fever, which occurs as a complication of Str. pyogenes infection with all serological types at a more or less constant rate of around 3 per cent, the attack rate in glomerulonephritis associated with streptococcal infection is highly variable, and extremes of 0.03 and 18 per cent have been observed. The disease may occur in semi-epidemic form, especially in school children. This may be taken to suggest that, unlike rheumatic fever, glomerulonephritis may reflect the variable distribution in time and space of nephritogenic strains of Str. pyogenes. 69 In apparent confirmation of this, it has been found that the majority of cases in this country which have been studied bacteriologically have been associated predominantly with Str. pyogenes type 12, a lesser number with type 4, and occasionally other serological types may be implicated. An apparently new type of Str. pyogenes, the Red Lake strain. occurring in an epidemic of nephritis on an Indian reservation has been described

Fred Helmer Care Control

also. 100 A similar association with type 12 has been observed also in Canada and in England. It is by no means certain that all type 12 strains are nephritogenic, and strains apparently differ among themselves in this respect. Other than this association with serotype, nephritogenic strains of *Str. pyogenes* are not differentiable from those which are not associated with kidney disease.

Glomerulonephritis differs from rheumatic fever also in that it does not tend to recur in the recovered individual, and it is supposed that an effective degree of immunity to the type-specific M antigen persists and that a hypersensitivity is not involved in the disease. Recovery usually seems to be complete, and there seems to be no evidence that chronic nephritis is causally related to prior streptococcal infection.

The disease has been reproduced in rabbits⁷³ and monkeys⁷⁴ by infection with nephritogenic type 12 strains of *Str. pyogenes* or with products of the bacteria administered repeatedly, and in mice with soluble streptococcal products in *in vivo* diffusion chambers.^{44, 96} Renal lesions have also been produced in experimental animals by inoculation of soluble antigen-antibody complexes^{60, 103} and in parabiosed animals.⁵⁰ The evidence shows that kidney pathology results from the antigen-antibody reactions following immunization to streptococcal antigen, and are an indirect, rather than a direct, consequence of the primary infection.

SUBACUTE BACTERIAL ENDOCARDITIS

Infection of the endocardium with the formation of ulcerative lesions may occur with many bacteria. 101 By far the most common are the α -hemolytic streptococci, but staphylococci, \(\beta\)-hemolytic streptococci, and, to a much lesser extent, pneumococci, gonococci. meningococci. Hemophilus, Brucella, Salmonella, etc., are found. With the more highly virulent bacteria the infection is an acute one, but the disease known as subacute bacterial endocarditis, which is no less fatal, is caused almost exclusively by an α -hemolytic streptococci, though in a very few instances anhemolytic streptococci have been implicated.

The infection of the heart valves may be

primary or secondary to a focus of infection elsewhere in the body, and an almost indispensable predisposing factor is congenital abnormality or prior damage, as by rheumatic infection, of the heart valves. The source of infection is often the tonsils and periapical infections of the teeth or lowgrade infection in the gums. There seems to be an occasional leakage of streptococci from these sources into the blood stream. and any disturbance of the infected areas, such as the extraction of teeth, tonsillectomy, and manipulation of an infected cervix. results in transient bacteremia. The bacteria are rapidly removed from the blood stream by phagocytic cells in the liver, spleen, bone marrow, and elsewhere in the body, but infection of the heart valves may occur when there is an abnormality. Such abnormality may, for example, be a consequence of cardiac damage occurring during an attack of rheumatic fever.

The infection of the endocardium is probably direct rather than from embolism in the smaller vessels at the attachment of the endocardial and subendocardial tissues. According to Grant, Wood, and Jones²⁶ the bacteria establish in small platelet thrombi on the valvular surfaces, but McNeal, Spence, and Slavkin⁵⁸ found that, in experimental endocarditis in the rabbit, the circulating bacteria are phagocytosed by the endothelial cells on the heart valves as well as elsewhere, but are not killed and produce local damage which is covered by a deposit of fibrin; the fibrin protects the streptococci to allow proliferation and the development of a local infection. In any case, during the course of the disease streptococci are shed into the blood stream and may be demonstrated by blood culture. It is significant, especially from the point of view of chemotherapy, that the lesion is not a superficially situated thrombus, but is, for all practical purposes, an abscess in the substance of the valve.

Species of green streptococci of both the viridans and enterococcus groups are responsible for this disease. In one study it was found that practically all of nearly 200 cultures of green streptococci from clinical sources, including subacute bacterial endocarditis, were either Str. salivarius or Str. faecalis; and in another 12 the most common species found was Str. mitis, Str. salivarius next, and Str. faecalis was found least often.

The disease process is, however, essentially the same regardless of the species of α -hemolytic streptococcus causing it.

PUERPERAL FEVER

Puerperal fever is a vague term in that some degree of pyrexia is not uncommon immediately following childbirth. A definite febrile response is probably in most instances associated with bacterial infection, but in mild cases the microorganisms are relatively avirulent. The severe infections are due almost entirely to streptococci, the majority Str. pyogenes. Infection with other β -hemolytic streptococci occurs, but when these are of groups other than Group A the infections are usually not severe. The anaerobic streptococci are second only to Str. pyogenes in importance, being the cause of possibly 20 to 25 per cent of cases of severe puerperal fever; the disease caused by these forms is not as rapidly fulminating as that caused by Str. pyogenes, but the case fatality rate is high, possibly 40 per cent. In fatal cases of puerperal fever the infection generalizes to fatal septicemia, and it is probable that the pronounced invasive qualities of the streptococci are responsible for their virulence under these circumstances.

A point that has been of primary interest is the source of the streptococci producing puerperal fever. It seems well established that Str. pyogenes occurs only rarely in the female genital tract and is rarely found before labor or during an afebrile puerperium. Lancefield and Hare,49 for example, reported a series of 855 cultures of the vagina of parturient women; one strain of Str. pyogenes was found among 65 strains isolated during an afebrile puerperium, and none among 13 strains isolated before labor. This and similar studies indicate that the source of infection with Str. pyogenes is exogenous rather than endogenous. The development of streptococcus typing and a reasonably precise definition of the immunological types has allowed the demonstration of the probable source of the infecting organisms. In one study, slightly over 50 per cent of the streptococci from the patient were identical with those from the nose and throat of attendants. and a little less than 25 per cent identical with those from the nose and throat of the patient. Colebrook⁹ reported similar results, the percentages being 58 and 38 respectively. Data such as these show that the source of infection is exogenous with respect to the genital tract and most probably the nose and throat of attending persons or the patient herself in 75 per cent or more of cases. The infection may be air- or dustborne, but it seems probable that the hands play a significant part in the transfer of infection.

The anaerobic streptococci, on the other hand, are normal inhabitants of the human vagina.⁹⁵ In the absence of precise immunological methods for their identification, it may be tentatively concluded that infection with these organisms to produce puerperal fever is endogenous for the most part.

Chapter Eighteen

THE PNEUMOCOCCI®

The bacterium most commonly found in pneumonia in man is a small lanceolate micrococcus which has been variously termed Micrococcus pneumoniae, M. lanceolatus, Streptococcus pneumoniae or, more briefly, the pneumococcus or Fränkel's pneumococcus. Diplococcus pneumoniae is now the commonly accepted formal name.

Of the generally recognized anatomical types of pneumonia-lobar or acute croupous pneumonia, bronchopneumonia or lobular pneumonia, and capillary bronchitis or bronchiolitis-lobar pneumonia is nearly always due to the pneumococcus, though other bacteria are occasionally involved. Perhaps the best quantitative data are those assembled by Rumreich and his co-workers⁴³ in a two-year study in six states representing high and low pneumonia rates. These are summarized in the accompanying table. It is evident that the pneumococcus is by far the commonest cause of pneumonia. The microorganisms associated with bronchopneumonia are varied, and their source is probably almost always the nasopharynx.45

RANGE CONTRACTOR OF STATE OF S

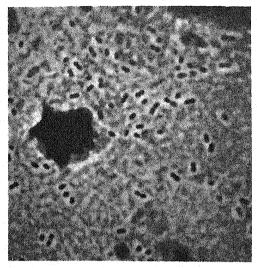

The pneumococcus was discovered independently in France in 1881 by Pasteur, who inoculated rabbits with the saliva of a child dead of rabies, and by Sternberg in the United States, but was not known to be associated with disease in man before the extensive investigations of Fränkel and Weichselbaum, who demonstrated conclusively the etiological relation of this bacterium to pneumonia in man.

Morphology and staining. The pneumococcus is typically a small, slightly elongated coccus, one end of which is pointed or lance-shaped. The cocci commonly occur in pairs (diplococci), but variations both in grouping and in size and form of individual cells are frequently observed. Chain formation is common, especially in artificial mediums, although the chains are usually shorter than those of *Str. pyogenes*. Oval and elongated bacillary forms sometimes occur. The pneumococcus is nonmotile and does not form spores. A well-defined capsule envelops the pneumococci in animal exudates but, except in certain strains or in certain

The Incidence of Etiological Agents in Pneumonia*

mediums, is less readily demonstrable in cultures grown outside the body. Capsules may often be found in milk cultures and in mediums containing blood or serum.

The pneumococcus is readily stained with the aniline dyes and is generally gram-positive, although there is a tendency to become gram-negative in older cultures, and occasional strains are found to be gram-negative. In stained preparations the capsule may often be seen as an unstained halo surrounding the cells; it may be stained by special methods.

The colonies of pneumococcus on infusion agar or blood agar are typically small, moist, translucent, and granular, with well-defined edges. These bacteria are α -hemolytic on blood agar, and the colonies appear surrounded by a zone of greenish discoloration on this medium and resemble the colonies of green-producing streptococci, so closely as to be practically indistinguishable from them.

Physiology. Some pneumococci grow upon the ordinary nutrient (beef extract) culture mediums but many do not,²⁵ and, in any case, growth is sparse. Nutritional requirements are complex. A number of semi-synthetic mediums have been developed, based on gelatin or casein hydrolysate, and supplemented with vitamins and various other growth accessory substances, and amino acids.^{1, 8, 9, 19, 40, 41} The requirement for added choline, nicotinic acid, and pantothenic acid appears to be quite general

among the serotypes, and biotin and ascorbic acid are required by some strains. Growth is often markedly stimulated by the inclusion of purines and pyrimidines, but these do not appear to be essential. Amino acid requirements are complex and varied from strain to strain. Of the common serotypes, type 3 appears to be more exacting, but strain differences may be as great, or greater, than differences between serotypes.

Growth on infusion mediums, particularly those enriched by the addition of whole blood, takes place at 37° C. Litmus milk is promptly acidified and often, but not invariably, coagulated. The temperature range over which these bacteria may be grown is relatively narrow (25° to 42° C.), and they are sensitive to variations in pH from the optimum of 7.8, the limiting acidity and alkalinity being 6.5 and 8.3 respectively. The pneumococcus is a facultative anaerobe, although certain other species of Diplococcus are obligate anaerobes.

In general, sugars are actively fermented with the production of large amounts of lactic acid and small amounts of volatile acid and ethyl alcohol. Differential fermentations are of no particular value in the classification of these microorganisms except in the case of inulin, which serves to differentiate the pneumococci and the green streptococci.

The pneumococci appear to be structurally delicate organisms and autolyze much more readily than most other kinds

TOXINS 455

of bacteria. Evidences of protein hydrolysis accompany autolysis, and it appears that lysis is a consequence of the activity of intracellular enzymes.39 Perhaps associated with the autolytic process is the lysis of pneumococci by bile and bile salts. The socalled bile solubility of pneumococci is practically a constant characteristic, although different strains vary in their sensitivity to bile as they do in the tendency to autolysis. Rabbit or ox bile may be used and added to a young broth culture in the proportion of 10 to 20 per cent. Solutions of pure bile salt (sodium taurocholate) are preferable to ox bile because they may be sterilized and the concentration (10 per cent) controlled. Heat-killed pneumococci are not bile-soluble. Sodium lauryl sulfate and similar detergents will also lyse pneumococci. 10, 20

Pneumococci may, therefore, be distinguished from streptococci by their bilesolubility and, less definitely, their ability to ferment inulin, in addition to their greater pathogenicity for mice and the characteristics of the colonies on agar.

Peroxide is found in considerable quantities in pneumococcus cultures after prolonged incubation because of the lack of catalase in these microorganisms. This, coupled with their sensitivity to peroxide, results in the autosterilization of cultures kept in the incubator for many days. Cultures in blood broth, however, remain viable for several weeks in the refrigerator, and the bacteria may be preserved for months in the cold in vacuum-desiccated spleens of infected mice.

The pneumococci are more sensitive to the bactericidal activity of the usual antiseptics than are many other bacteria. Soaps, such as ricinoleate and oleate, are pneumococcidal in relatively high dilutions, 0.04 and 0.004 per cent respectively, and other substances such as phenol and mercuric chloride are also highly effective in the destruction of these bacteria. Quinine and some of its derivatives have antipneumococcal activity but do not inhibit α -hemolytic streptococci; optochin-containing discs, similar to antibiotic discs, are available for the differentiation of pneumococcus and green streptococci.

Toxins. The severe intoxication observed in pneumococcal infection in man is suggestive of the formation of some toxin by this

bacterium. The existence of such a toxin has never been demonstrated, however, and the pneumococcus does not produce a toxin analogous to those of the diphtheria and tetanus bacilli.

Other toxic substances are produced by this microorganism. That there is α -hemolysis on blood plates has already been noted. and there is in addition a filterable hemolysin active on sheep, guinea pig, and human erythrocytes.35 The concentrated hemolysin is reported to have lethal and dermotoxic properties. The pneumococcus also produces a leucocidin³⁷ and a necrotizing substance similar to that formed by some of the staphylococci. Many strains produce hyaluronidase, especially when cultivated in mediums containing hyaluronic acid.27 A purpura-producing substance which is nonantigenic and appears to be a cleavage product of pneumococcal protein has been described by a number of workers. Injected into white mice, extracts of pneumococci produce a purpuric condition manifested as a dark blue discoloration of the skin of the feet, tail, ears, nose, and genitals.28 It has been observed too that virulent strains are able to utilize extracellular breakdown products of nucleic acids, which stimulate both respiration rate and DNA synthesis. 17

Although preparations containing these activities have been reported to increase the virulence of relatively avirulent pneumococcus strains when injected simultaneously with the bacteria, the virulence of pneumococci is directly dependent, not on the formation of such toxic substances, but on the production of specific soluble substance and encapsulation.

Classification. The pneumococci are closely related to the streptococci, but the degree of intimacy of the relationship is as yet open to question. Some workers regard these microorganisms as but a species of streptococcus and designate them as Str. pneumoniae. In general, however, it is customary to consider the pneumococci as a distinct genus, a practice which is justified by considerations of the sum of the characteristics of the pneumococci and the clinical and epidemiological aspects of the pneumonias. According to Bergey's classification, the tribe Streptococceae is made up of three genera: (1) Diplococcus, of which the type species is D. pneumoniae or the pneumococcus; (2) Streptococcus, with Str. pyogenes as the type species; and (3) Leuconostoc, a group of gas-forming, chainproducing cocci found in milk, fermenting vegetables, and slimy sugar solutions.

The genus Diplococcus includes six species in all, the five in addition to the pneumococcus being obligate anaerobes. *D. paleopneumoniae* closely resembles the pneumococcus except for its anaerobic character, occurs normally in the buccalpharyngeal cavity, and is reported to be highly pathogenic. *D. plagarumbelli* has been found in septic wounds, and the remainder, *D. magnus*, *D. constellatus*, and *D. morbillorum*, appear to be normal inhabitants of the mouth and intestinal tract and have been found in lymphoid tissue such as in the tonsils and appendix.

Pneumococcus types. A point that has been of somewhat more interest than the formal taxonomic position of the pneumococci is the subdivision of these bacteria into types. The pneumococci contain two kinds to antigen. One, the so-called somatic antigen, is a constituent of the cell substance proper and is immunologically identical in all pneumococci. The other, the polysaccharide haptene or specific soluble substance (SSS), is type-specific and serves to differentiate the immunological types of pneumococci from one another. The polysaccharide of type 3 has been the most thoroughly studied chemically and types 1, 2, 5 and 6 to a lesser extent (Chap. Three).23, 29 These substances have been isolated from most of the other types also. The presence of SSS masks the somatic antigen, and antiserums to encapsulated pneumococci are sharply type-specific. These immunological types are designated by numerals, and the numbering of the types, although purely arbitrary, is a generally accepted convention.

Observations by Dochez and Gillespie in 1913 showed that the pneumococci found in cases of lobar pneumonia can be divided into four distinct groups, designated as types 1, 2, and 3 and Group IV, on the basis of specific agglutination and protection tests. Of these, types 1, 2, and 3, found in the majority of cases of pneumonia and producing the most severe types of infection, have specific immunological character, while Group IV is immunologically heterogeneous and is made up of all pneumococci not belonging to the first three types.

The types making up Group IV were then sorted out by Cooper and her associates

in this country, and by Danish workers, to give a great many serological types of pneumococcus. There are two different nomenclatures for the pneumococcal types:30,31 the Danish system which is an extension of Cooper's system in which serologically related types are grouped together as subtypes, and the system prepared by Eddy¹² under the auspices of the U.S. Public Health Service and the American Public Health Association, in which the differentiable types are given consecutive numbers irrespective of antigenic relationships. There are 80 differentiable types, but some are antigenically related to one another; there is, for example, partial cross-reaction between types 2 and and 5, between 3 and 8, between 7 and 18, and between 15 and 30. Rarely, mixed types, containing antigens characteristic of more than one differentiable type, are found.18 Mixed types have been produced artificially by transformation reactions⁵ (see below), and such types are considered to contain two capsular genomes, one mutated and the other normal, which interact to give the observed phenotypic expression.6

Diblococcus mucosus. These nological types are culturally indistinguishable with the exception of type 3, which stands somewhat apart from the other pneumococci in that it produces a heavy mucoid growth because of its luxuriant capsule formation. It is considered by some to be a separate species, D. mucosus. Many cultures show a marked tendency to form chains, and the dividing line between D. mucosus and "Str. mucosus" is not a sharp one, if indeed any distinction should be made. These coccoid, heavily capsulated bacteria for the most part ferment inulin and are soluble in bile, so that the tendency is to group them with the pneumococci rather than the streptococi. A few mucoid strains have been reported which are bileinsoluble and noninulin-fermenting.

Pneumococcus typing. The serological typing of pneumococci may be carried out in a number of ways but is not a routine diagnostic procedure. The various methods that have been developed are basically immunological but differ in technical detail. The immunological procedures are of three kinds: (1) the agglutination of the pneumococci with type-specific antiserum, (2) the precipitation of SSS with type-specific antiserum, and (3) the Quellung reaction. The first two have been discussed in pre-

TYPES 457

vious sections and need not be considered further here.

The Ouellung phenomenon was described by Neufeld in 1902 and is in general use. A suspension of pneumococci is mixed with undiluted antiserum (rabbit serum is preferable to horse serum) on a slide or cover glass, a small amount of Löffler's alkaline methylene blue is added to facilitate observation, and the preparation is examined under the microscope. In the presence of homologous immune serum there is a marked apparent swelling of the capsule without any obvious change in the size of the bacterial cell itself; no such swelling is observed with heterologous serums. The reaction takes place rapidly, and the swelling is usually apparent within a few minutes. This apparent swelling of the capsule in the presence of specific antiserum is discussed elsewhere (Chap. Three).

The use of serum pools considerably facilitates typing, especially the identification of the higher types. The incidence of the various types determines the most advantageous combinations of antiserums. A group of combinations often recommended for use in this country is:

(a) 1, 2, 7

(b) 3, 4, 5, 6, 8

(c) 9, 12, 14, 15, 17

(d) 10, 11, 13, 20, 22, 24

(e) 16, 18, 19, 21, 28

(f) 23, 25, 27, 29, 31, 32

Monospecific antiserums are required also. The pneumococcus to be typed is tested with each pool and then with the component antiserums of the pool with which it reacts. Thus a pneumococcus may be identified in 12 or fewer tests. 13, 14, 15

Variation. The smooth and rough variants that have been found in a variety of bacteria may also be observed in the pneumococcus. As in other cases, there are various intermediate colonial types between the two extremes, and the pneumococcus is virulent in the smooth form and almost completely avirulent in the rough form. The change from smooth to rough is reflected in the microscopic morphology of the cells as a loss of capsule. According to Austrian, colonial type involves the formation of filaments of pneumococci as well as capsule formation; the typical virulent strain is the nonfilamentous capsulated

form. These factors vary independently, as shown by transformation reactions, to give the possible combinations, including a filamentous noncapsulated type which had not been explicitly recognized earlier.

Since type specificity is determined by the SSS, it follows that the change from smooth to rough is accompanied by a complete loss of type specificity; the somatic antigen is predominant and, irrespective of original type, the pneumococci become immunologically identical. The dissociative change may be reversed, although with difficulty, by animal passage or by cultivating the R form in the presence of anti-R immune serum or in the presence of heat-killed cells from a smooth culture.

Transformation of types. The experimental interconversion of pneumococcal types by direct transduction using an R form of pneumococcus and polymerized deoxyribonucleic acid prepared from a heterologous type has been described elsewhere (Chap. Seven) together with changes in serotype and other characteristics by phage-mediated transduction. These phenomena have been intensively studied with the pneumococcus, but the extent to which such changes may occur in nature is unknown.

Pathogenicity for man.21 As indicated above, lobar pneumonia is the most important pneumococcal infection in man. The bacteria are not confined to the lung, for they may migrate from this seat of infection through the nasal passages or be distributed via the vascular system to various parts of the body, to give rise to localized foci of infection. Pneumococcemia is of frequent occurrence; in one series of cases studied48 over a 14-year period, bacteremia averaged 22.8 per cent, the annual averages ranging from 16.4 to 49 per cent. A number of workers emphasize the prognostic value of blood culture, and in most instances both the case fatality rate and the incidence of purulent complications are considerably higher when pneumococci are present in the blood stream.7

Among the pathological processes that occur as complications and sequelae of pneumococcal pneumonia, or, it may be noted, as independent and primary affections, are inflammations of the pleura, pericardium, and meninges. The last continues to be a significant problem, for the case fatality rate is extremely high, and it does

angendere in Tokanish indist

not respond to chemotherapy as well as many of the other pneumococcal infections.^{2, 42, 47} Meningitis and otitis media are frequently secondary to pneumonia, and the connection between inflammation of the middle ear and meningeal infection has often been observed.³⁶

There appear to be few, if any, organs or tissues that are not under some circumstances subject to attack. Sinusitis, parotitis, conjunctivitis, peritonitis, and a great variety of other affections are occasionally due to pneumococci. In general, pneumococcal infections of this kind tend to a more favorable outcome than similar infections with streptococci or staphylococci.

Resistance to pneumococcal infection is, in large part, a matter of individual predisposition, and the mere presence of pneumococci in the upper respiratory tract is not sufficient to bring about pulmonary infection. Specific immunity plays a negligible part in resistance, but the complex of factors associated with a state of physiological wellbeing is of the greatest significance. A preliminary depression of resistance by other infections, severe or sudden exposure to cold, fatigue, and other predisposing factors is an almost invariable preliminary to pneumococcal infection. The part played by pneumococcal pneumonia in the fatal termination of many diseases, for example, is well known.

The pathogenicity of pneumococcus types. The case fatality of pneumococcal pneu-

monia is relatively high and indicative of the pathogenicity of these bacteria once they have become established in the lungs. The pneumococcus types differ from one another in this respect; the case fatality in type 1 infections is 25 to 30 per cent, that of type 2 about 40 per cent, that of type 3, 40 to 60 per cent, and that of Group IV infections perhaps 15 to 20 per cent. Because of the relatively recent differentiation of the types comprising Group IV, data on casefatality rates for these types are very meager as yet. The frequency of occurrence of the pneumococcal types in lobar pneumonia and bronchopneumonia is given in figure 89. Here the 10 leading types are: 1, 2, 3, 4, 5, 6, 7, 8, 14, and 19. In some series, type 2 is more frequent than type 3, and in others, including this one, the reverse is true. In a subsequent study of type incidence in the period 1952-1957, the commonest types were 3, 7, and 1, in that order, and in that series type 2 was rare.4

Pneumococcus carriers. As a strict parasite, the pneumococcus is found in man rather than in his environment. Healthy carriers of these bacteria are common; 40 to 60 per cent of groups of persons examined have been found to harbor pneumococci in the upper respiratory tract. This proportion is variable, being relatively high during the cold months of the year and higher among groups of contacts than among noncontacts. The carrier state is not permanent but rather sporadic and intermittent; many

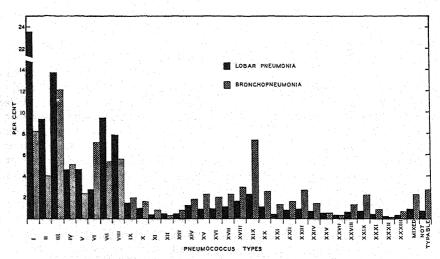

Figure 89. The incidence of pneumococcus types in lobar and bronchopneumonia, observed in a two-year survey in California, Colorado, Illinois, Louisiana, New Jersey, and Missouri, in which pneumococci from 12,447 cases of lobar pneumonia and 3847 of bronchopneumonia were typed. The relative predominance of type 3 over type 2 is sometimes observed. Note the more common occurrence of higher types in bronchopneumonia, the relative incidence of mixed types; *i.e.*, those reacting to more than one antiserum, and the incidence of types other than the first 33. (Data from Rumreich *et al.*)

^{*}Modified from Heffron.21

persons may carry these bacteria for a short time, particularly while having colds and other infections of the upper respiratory tract, while others may carry them for longer periods. There is also a seasonal fluctuation in that increased numbers are found in the winter months.

The great majority of pneumococci found in carriers are the relatively less virulent types of Group IV. Types 1, 2, and 3 are much less frequently found, but an appreciable portion of the population may harbor these types at any one time (see table). In the study made by Smillie, Calderone, and Onslow,⁴⁴ almost every type of pneumococcus was encountered; many individuals carried two or more types simultaneously. The types most commonly found were 3, 7, 21, 25, and 11 in that order of frequency. It is not clear whether an appreciably effective immunity is developed by the carrier.

The epidemiology of pneumococcal pneumonia. Pneumococci are disseminated chiefly through the secretions and discharges of the mouth and upper respiratory tract by direct contact between persons. Droplet infection undoubtedly plays a large part in the transmission of these microorganisms and perhaps accounts for the seasonal incidence of the disease and the increased frequency of carriers during the cold months of the year.

While it is obvious that pneumococcal infection is always exogenous in the last analysis, for practical purposes it is probably endogenous in a large proportion of cases. With a high carrier rate pneumococci are frequently present in the normal individual, and when resistance is reduced to a sufficiently low level they are able to set up an infection. The high incidence of pneumo-

cocci of types 1 and 2 as contrasted with the low carrier incidence of these types, together with the occurrence of seeming epidemics of pneumococcal pneumonia on a small scale, has been regarded by some as evidence of exogenous infection. It is more probable, however, that the greater virulence of some pneumococcus types operates as a selective factor to disturb the random distribution of types in pneumococcal pneumonia. It is known, for example, that minor respiratory infections may be common or epidemic in small groups such as a family. If a given type of pneumococcus of high virulence invades and spreads within the group so that a high proportion of the individuals become carriers, the operation of factors which reduce resistance in the group may result in one or more members coming down with pneumonia due to the type carried. Such a sequence of events was observed in a group of children in a nursery.46 The group was invaded by a virulent type 14 pneumococcus which caused no harm, but when the individual developed an acute respiratory infection, the dormant pneumococcus spread to the middle ear, conjunctivas, and lungs. Such children were sent to the hospital ward and carried the pneumococcus, which spread to most of the children there. Again, the infection was activated, sometimes with serious consequences, on the development of respiratory infection. Under appropriate circumstances pneumococcal pneumonia may occur in epidemic form. One such epidemic, occurring among military personnel, which was studied in detail,24 showed too that the most significant factors were the carrier rate, and the rate of nonbacterial respiratory disease as a predisposing factor.

Other epidemiological characteristics of

[†]The incidence of types is greater than the incidence of carriers because in some instances more than one type was found.

pneumococcal pneumonia include seasonal incidence, which corresponds roughly with the carrier rate; the age incidence, characterized by high morbidity and mortality in infants and the aged; the higher incidence in males than in females; and the apparent greater susceptibility of the Negro as contrasted with the white race.

Bacteriological diagnosis of pneumococcal infections.32 The pneumococcus may be isolated by culture or animal inoculation from specimens such as sputum, pleural exudate, blood, spinal fluid, and pus. Blood agar is the medium of choice, the bacteria growing up in 24 hours as small colonies surrounded by a zone of green hemolysis. It is not possible to distinguish them from α -hemolytic streptococci by colonial or microscopic morphology, but differentiation may be made by the fermentation of inulin and bile solubility of the pneumococcus and its immunological reactions. Blood specimens are cultured in buffered dextrose veal infusion broth, containing 5 mg. per 100 ml. of p-aminobenzoic acid if the individual is undergoing sulfonamide therapy. A portion of sputum, washed in three changes of sterile saline and emulsified in saline, may be inoculated intraperitoneally in a white mouse. With virulent strains the animal will show signs of illness in five to eight hours, and microscopic examination of smears of peritoneal exudate will show large numbers of encapsulated diplococci.

The pneumococcus is identified and typed with antiserum, usually by the Ouellung reaction though agglutination and precipitin tests may be used also. When large numbers of the bacteria are present in sputum, the typing may be done directly without culture or mouse inoculation, but since the Quellung reaction is inhibited in the presence of large amounts of SSS, negative reactions are not significant. Typing is readily carried out, as indicated earlier, on pneumococci present in mouse peritoneal exudate cultures but is no longer carried out except for special purposes, since type-specific serum therapy has been practically entirely supplanted by chemotherapy.

Chemotherapy. The pneumococci are uniformly susceptible to the sulfonamides and the commonly used antibiotics. The incidence of naturally occurring drug-resistant strains has been negligible, and determination of drug sensitivity is not yet an essential part of the chemotherapy of these

infections. *In vitro* the pneumococci are approximately as sensitive to these drugs as is *Str. pyogenes*. In pneumococcal meningitis, combined therapy with sulfonamide and penicillin has been reported to give better results than either alone; it has been reported that sulfonamide reduced the case fatality rate to 73 per cent, penicillin to 50 per cent and combined therapy to 29 per cent.

Pathogenicity for lower animals. The susceptibility of the usual laboratory animals to pneumococcal infection is variable. ranging from the highly susceptible mouse and rabbit through the less sensitive guinea pig to the cat, dog, chicken, and pigeon, which are highly resistant. Rare instances of naturally occurring infections in the usual experimental animals have been reported; for example, an epizootic of type 19 pneumococcal infection in the guinea pig has been described,26 and one of type 2 infection in laboratory rats.34 Animal experiments with the pneumococcus present an example of the general law that susceptibility is characterized by general septicemic infection. resistance by the occurrence of a localized process. The mouse and the rabbit³⁸ develop rapidly fatal septicemia, and in these animals lung lesions, when they occur at all, are slight and usually limited to the bronchopneumonic type. It is possible to produce typical lobar pneumonia in the rabbit by carefully balancing the susceptibility of the animal and the virulence of the bacterium through the use of attenuated cultures or previous partial immunization.

Resistant animals, such as the dog, show an approximation toward the type of pneumococcal infection observed in man, and lobar pneumonia may be produced in monkeys by intratracheal inoculation. The lesions produced in monkeys were considered identical with those in human lobar pneumonia. It is of some interest that pneumococci were found in the blood within six hours after their introduction into the trachea and before the signs of pneumonia appeared, suggesting the bronchogenic rather than the hematogenous origin of the infection.

Man, therefore, may be regarded as an animal of rather high normal resistance. This resistance may, however, be so reduced as to permit the production of localized manifestations, which in still more susceptible individuals may lead to fatal septicemia. In some cases death is due to

overwhelming interference with respiration caused by the local pulmonary lesions, and in others to a toxemia.

Immunity. Experimental animals may be actively immunized against pneumococcal infection by the injection of vaccines of the smooth, virulent bacteria, although the immunity is not of long duration, i.e., not more than a few months. The development of the immune state is accompanied by the appearance of antibodies, precipitins, agglutinins, and the like, as well as a protective quality in the blood serum. In man the situation is somewhat obscure; there is undoubtedly an intimate relation between recovery and the appearance of humoral antibodies, but immunity following infection is slight and transitory, and one attack may succeed another after a short interval. Active immunity in experimental animals is typespecific, however, and it is not improbable that under natural conditions different immunological types may participate in successive attacks.

The question of active immunization of man to pneumococcal infection is of continued interest. Results suggestive of its value were obtained from mass inoculation studies in 1918-1919 in this country. It has been shown²² that the inoculation of typespecific polysaccharides induces an antibody response which reaches a peak within six weeks and persists for about six months: booster inoculation during the following 18 months was not effective in raising the diminishing titers. It has been found³³ also that such immunization significantly reduced both carrier rate and cases of infection with the pneumococcus types immunized against, though not the incidence of other types. In the aggregate, then, these data suggest that an appreciable degree of effective immunity may be produced by immunization procedures.

The results of the therapeutic use of antiserum are variable, being excellent with some types of pneumococci and not with others. Serum therapy was formerly of great practical importance, but with the introduction of effective chemotherapeutic agents is no longer used.

Chapter Nineteen

THE GRAM-NEGATIVE PATHOGENIC COCCI (NEISSERIA)

The Gonococcus and the Meningococcus

The gonococcus and the meningococcus are the chief representatives of a small group of closely related bacteria whose other members are nonpathogenic inhabitants of the mouth and upper respiratory tract of man.⁵⁸ Two groups of species are separated from

one another on the basis of pigment production, and further differentiation is made by means of fermentation reactions. Pigmented varieties are frequently found in the nasopharynx (Neisseria flava I, II, III).

The Gonococcus

Neisser in 1879 first called attention to the constant presence of a peculiar coccus in gonorrheal pus. In cases of gonorrhea of recent origin this was the sole organism found; it not only occurred in the urethral and vaginal discharges of ordinary gonorrhea, but was present in the exudate in conjunctivitis due to gonorrheal infection. Pure cultures of this microorganism were isolated in 1885 by Bumm, who succeeded in demonstrating its etiological relation to gonorrhea by the inoculation of human volunteers. This bacterium, known generally as the gonococcus, has been termed Micrococcus gonorrhoeae and Diplococcus gonorrhoeae, but the genus Neisseria is now more or less generally accepted, and this bacterium is properly known as N. gonorrhoeae.

Morphology and staining. In preparations made from gonorrheal pus the cells of the gonococcus occur in pairs, with the flattened sides in juxtaposition; the appearance in stained preparations resembles that of a coffee bean. In pure culture the cocci appear

as oval or spherical and are often aggregated in irregular masses without the typical diplococcus arrangement. In pus smears the gonococcus occurs almost entirely within the leucocytes; frequently enormous numbers may be found packed within a single phagocyte. In the earliest stages of infection gonococci may be found extracellularly, and the same is true of cases of gonorrhea of long standing. The gonococcus is nonmotile and does not form spores.

The colonies of the gonococcus are small, translucent, finely granular with lobate margin and grayish white with a pearly opalescence when viewed by transmitted light. Larger colonies may be formed on special mediums. Colonial appearance is, however, subject to variation (see below).

Unlike the other pyogenic cocci, the gonococcus and related forms are gram-negative, a staining characteristic that is of considerable diagnostic value, since it serves to differentiate the gonococcus from other cocci present in the urethral or vulvovaginal

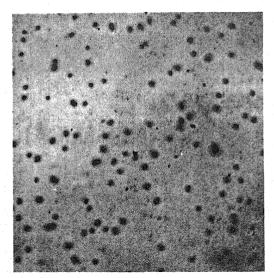

Figure 90. The gonococcus from pure culture. Fuchsin; \times 1050.

tracts. Other gram-negative cocci may be found occasionally, sometimes within the leucocytes, but they are rare. The tendency to decolorization in the Gram stain is variable. Some strains decolorize much more readily than others, and gonococci embedded in masses of pus may retain the stain; hence the preparation of thin, uniform films is highly desirable. The gonococcus stains with the aniline dyes, but polychrome stains, such as Pappenheim's stain,² are more useful. Intracellular granules may be found in stained preparations, but in general the gonococci from young cultures stain evenly, while older cultures (24 hours and older) contain large swollen involution forms, which may stain poorly.

Physiology. In its nutritive requirements the gonococcus is one of the most fastidious bacteria, particularly upon primary isolation, and an enriched medium is required for cultivation. Earlier mediums were enriched by the addition of ascitic and hydrocele fluid. Chocolate (heated blood) agar has been the most widely used, and the basal medium may be enriched with horse plasma and hemoglobin, and sometimes Nile blue A is added.

The nutritional requirements of the gonococcus are complex although some strains may be grown on a tryptic digest—glucose agar containing added cystine, and relatively complex synthetic mediums have been devised which will support growth.²⁸ Stock strains are commonly less exacting than recently isolated strains, and it is likely that growth requirements are more accurately reflected in the mediums required for isolation or growth of fresh isolates. Such strains do appear to require added glutamine and cocarboxylase since they apparently cannot phosphorylate thiamin, and glutathione is required by some strains.

A sufficient supply of moisture is essential; there should be water of condensation on the tubes or plates, and the atmosphere of the incubator should be kept saturated with water. Incubation in an atmosphere of increased CO₂ tension, about 10 per cent, greatly improves growth and is a practical necessity in primary isolation.²²

With continued cultivation on laboratory mediums, the gonococcus appears to become somewhat less fastidious, and some strains may eventually grow upon the ordinary infusion mediums. The preservation of cultures is difficult, however, for the gonococci die off in two to three days at room temperature and in six to eight days at 37° C., but will live longer when kept in the cold. Even upon continued transfer the gonococci die off, and cultures are often lost. The optimum temperature for growth is 37° C., growth does not occur below 30° C., and temperatures of 40° to 41° C. are definitely harmful. The gonococcus will grow under anaerobic conditions but is essentially aerobic in character

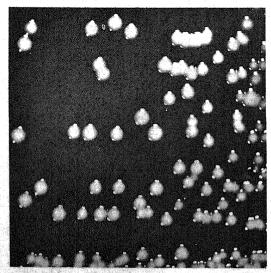

Figure 91. Colonies of the gonococcus on blood agar, × 6.

With respect to deleterious influences the gonococcus is a delicate microorganism. It is readily killed by heat, as indicated above, and by dilute antiseptics; 1 per cent phenol, for example, kills in one to three minutes. It is remarkably sensitive to certain of the flavine dyes and is rapidly destroyed by silver salts.

The gonococcus is sensitive to drying and, under ordinary conditions, can survive exposure to the air for only a very short time—one to two hours—although in masses of dried pus it may live exceptionally for six to seven weeks. Unlike most gram-negative bacteria, it is sensitive to penicillin as well as to streptomycin and the tetracyclines.

The gonococcus is not very active biochemically. Glucose is fermented, principally to lactic acid, but many other sugars

SERVE TO SEE THE

are not attacked, indol is not produced, nitrates are not reduced, and no change is produced in litmus milk. Its fermentation of glucose and failure to ferment maltose distinguish it from the other nonpigmented Neisseria; the fermentation reactions are reliable and used for purposes of identification.48 but the basal medium used must be such as to support growth of the microorganism.31 Catalase is produced, and a characteristic that has been turned to practical differential use is the formation of indophenol oxidase. The specimen is cultured on 10 per cent heated blood (chocolate) agar in an atmosphere containing 8 per cent carbon dioxide, followed by 24 hours' incubation in air. A 1 per cent solution of tetramethyl-p-phenylenediamine is poured on the incubated plate and poured off again

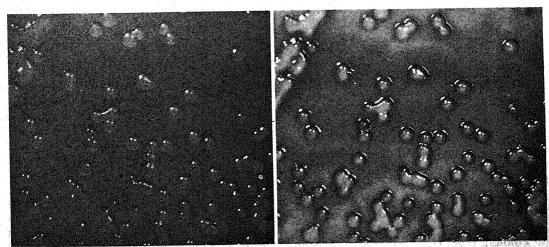

Figure 92. The oxidase test for the identification of gonococcus colonies. Pure culture on blood agar. Left, gonococcus colonies before the application of tetramethyl-p-phenylenediamine solution. immediately or sprayed on with a nasal atomizer. Colonies of bacteria forming indophenol oxidase turn a bright purple color. The bacteria are not immediately killed and may be subcultured within half an hour. This so-called oxidase reaction, coupled with the examination of smears for gramnegative intracellular diplococci, is generally used in the laboratory diagnosis of gonorrhea.

Toxins. Other than a weak hemolysin, the gonococci apparently form no extracellular toxic substances, but the cell substance is toxic to experimental animals on parenteral inoculation and has been reported to produce suppuration when instilled into the human urethra. The toxicity is extractable in dilute alkali as a "nucleoprotein," and from this material or from the intact bacteria by trichloracetic acid or diethylene glycol, in the latter instance behaving like a Boivin antigen, e.g., the endotoxin of the gram-negative bacilli. It was subsequently found to be extracted in phenol by the Westphal method to give a toxic lipopolysaccharide which could then be purified by fractional precipitation with acetone. This substance is similar to the gram-negative bacillus endotoxins as typified by colon bacillus endotoxin, but on analysis has been found to differ significantly in lacking diaminopimelic acid and glycine and in lesser content of other amino compounds.65 The contained carbohydrate has been found to consist of D-glucosamine, glucose, and galactose, the amino acids presumably serving to link the sugar and lipid components in the intact molecule. The pharmacological activity of the gonococcal endotoxin appears to be nonspecific and overtly similar to that of the other endotoxins. Its role in the pathogenesis of gonococcal infections is uncertain.

Variation. Numerous workers have observed that the cultural characteristics of the gonococcus are subject to considerable variation. It has been found that two types of colonies may be observed which appear to be correlated with immunological type. The one, designated as type I, is a large, irregular, flattened, translucent colony which appears dark gold in color by oblique transmitted light.³³ On continued incubation papillae appear on the surface. The other type of colony, type II, is somewhat smaller, round, raised with slightly convex uneven surface, and opaque. Type I colonies are generally recovered from acute gonorrhea, while type II are found in old laboratory strains and, sometimes, in chronic gonorrhea. The papillae are thought to represent the first step in transition toward the type II form. The relation of these forms to the dissociative changes of other bacteria is uncertain. Small colony variants, presumably arising from a dissociative process, have been produced experimentally and have also been found on primary isolation from clinical material.⁴⁷

Drug resistance. Resistance of gonococci to the sulfonamides and antibiotics is readily acquired under experimental conditions, and resistant strains appear in nature coincident with the general application of chemotherapeutic agents. When the sulfonamides were introduced into general use as chemotherapeutic agents in 1936-37, 80 to 90 per cent of infections could be cured with them. An increase in the proportion of refractory infections became noticeable in three or four years, a sharp increase occurred in 1942-43 from 25-35 per cent to 50 per cent, and by the late 1940's as few as 15 per cent of infections in some areas responded to sulfonamide therapy.74 Gonococcus strains isolated from refractory infections usually prove to be resistant on laboratory examination, many, but not all, of them producing p-aminobenzoic acid in excess amounts.

Meantime penicillin therapy became available in the middle 1940's and has been widely used, usually as repository penicillin, except in France where streptomycin has been preferred to avoid masking of concurrent syphilitic infection. Subsequently other antibiotics, the tetracyclines, erythromycin, chloramphenicol, etc., effective in the treatment of gonorrhea, became available also but have not been generally used. Strains of gonococci resistant to penicillin did not appear in increased numbers until about 10 years after its introduction, but by the late 1950's it was apparent that 20 per cent or more of strains isolated in many areas were resistant to high concentrations, 20-fold or more the original sensitivity, not ordinarily achieved as blood levels. 6, 8, 41, 56, 68 A temporary, and effective, expedient has been the use of larger doses of the antibiotic. Concurrently, strains of gonococci resistant to streptomycin have increased in number in France, with 75 per cent of strains resistant to 50 μ g./ml. or more, and more than 20 per cent resistant to 1000 µg./ml., in contrast to an original sensitivity level of perhaps 5-10 μg./ml. 16, 57

Increase in the proportion of resistant strains coincides with the use of the chemotherapeutic agent. There seems to have been no significant increase in penicillin-resistant strains of gonococci in France, nor an increase in streptomycin-resistant strains in other European countries and the United States where penicillin has been used. The tendency to reversion to sensitivity when the chemotherapeutic agent is discontinued. apparent in some other bacteria, e.g., the staphylococci, is indicated by the decline in the proportion of sulfonamide-resistant strains, which by 1958 reached approximately the level which prevailed when sulfonamide therapy was generally introduced.10

Clinical refractoriness to penicillin therapy is not necessarily always a consequence of infection with a resistant strain of gonococcus. Some cases may be refractory because of failure of the antibiotic to affect phagocytosed gonococci, which have been shown experimentally to survive considerable increases in concentration of penicillin over the minimal inhibitory concentrations. Further, the picture of relative efficacy of chemotherapy may be clouded by the by-no-means uncommon occurrence of nongonorrheal urethritis, 27, 50, 51 which may not be affected by the chemotherapeutic agents used.

Antigenic structure. The gonococci are apparently of uncertain antigenic structure as assayed by conventional methods of antigenic analysis.54 Certain of the antigens appear to be thermostable, and thermostable and thermolabile partial antigens occur also, some of which may function as blocking antigens, and antigenicities appear to be shared with meningococcus and some strains of Pasteurella. Gonococcus strains not only differ when freshly isolated, but also apparently change antigenically on continued subculture. Studies with soluble antigen, prepared by extraction with dilute alkali and precipitation with ethanol from neutral solution, in the passive hemolysis reaction have given more consistent results. Two main antigens are demonstrable by this technique, the one associated with colonial type I which is shared with meningococcus, and the other with type II. The dual nature of the antigenicity is also indicated by differentiation of the antigenicity which sensitizes red cells to immune lysis in the presence of antiserum from that which fixes comple-

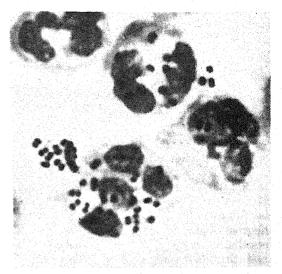

Figure 93. Urethral smear from gonorrhea. Note the intracellular and extracellular positions of the gonococci and their typical coffee-bean shape and arrangement in pairs. Gram stain; × 2400.

ment. The relation of this antigenicity to the lipopolysaccharide endotoxin has not yet been described, but it is heat-stable and presumably polysaccharide in nature. Antiserum to the alkali-extracted endotoxin described above is protective in the mouse.

Further study has shown that the heatstable antigenic complex contains at least six antigens shared with the meningococcus, and which occur in varied combinations,78 and also that freshly isolated strains of gonococcus are often inagglutinable in antiserums to these antigens.⁷⁷ The last has been taken to suggest that fresh isolates may contain a K-type antigen (Chap. Twenty), labile in that it is readily lost, and functioning as a blocking antigen. The existence of this kind of antigen in the gonococcus has been demonstrated by the fluorescent antibody technique.¹³ It appears to be sharply specific for the gonococcus, and is present in a relatively large amount on gonococci in acute infections, i.e., as observed in urethral smears, and in very young cultures, but has largely disappeared in 30-hour cultures.

Pathogenicity for man.²⁶ Few diseases are so widely disseminated through all classes of society as gonorrhea. Precise information as to the incidence of the disease is not available. It is estimated that in the United States no more than 10 to 20 per cent of cases are reported, and that gonorrhea is the third most common infection (after mea-

sles and streptococcal infections).²⁵ In 1944 it was predicted that, with the means, penicillin, available, the virtual eradication of gonorrhea could be anticipated. In that year 301,000 cases were reported, and the number rose to 401,000 in 1947, subsequently declining somewhat to stabilize, since 1952, at about 220,000 cases reported per year. More than half of these are persons under 25 years, with a modal age of 18 for females and 22 for males.⁶

The gonococcus usually gains entrance to the tissues after deposition on the surface by burrowing through the superficial epithelium, between the cells, to reach subepithelial connective tissue from which it spreads by direct continuity or by the lymphatic or blood vessels. Stratified squamous epithelium is more resistant to this penetration than columnar epithelium. The characteristic reaction within the tissues is a dense cellular infiltration of polymorphonuclear leucocytes, plasma and mast cells, and these are eventually replaced by fibrous tissue. In the male, epididymitis, chronic urethritis and stricture, and other inflammatory conditions develop, and in the female, the entire genitourinary tract may be involved, and the fallopian tubes, the ovaries, and the peritoneum are not uncommonly invaded. The gonococcus may also invade the blood stream from local lesions and be carried to various parts of the body to give rise to a variety of extragenital

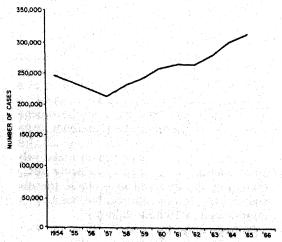

Figure 94. The prevalence of gonorrhea in the United States as indicated by reported civilian cases during the period 1955-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

lesions. Especial predilection is shown for the synovial membranes of the joints, where it causes the so-called gonorrheal rheumatism, and for the heart valves, where it produces endocarditis. Local or general complications occur in perhaps 30 per cent of all cases. Gonococcal meningitis occurs, perhaps more frequently than formerly thought. There has been a general belief that the incidence of complications—epididymitis, prostatitis, salpingitis and arthritis—has been less since the introduction of effective chemotherapy, but this appears to be open to question.²⁰

Once established, untreated gonococcal infection persists for a long time; five to 15 years' duration has been reported. Exclusion of reinfection is a difficult matter, but infection of seven years' duration without reinfection has been observed. Subclinical infection may occur, with or without transient symptoms, and individuals so infected may act as carriers. The clinical disease is often not as overt in the female, and infected promiscuous females constitute an important reservoir of infection.⁷⁶

Epidemiology.³⁵ Gonorrheal vulvovaginitis occurs in epidemic form in little girls, and in these instances the infection is transmitted by bedclothes, towels, common bathtubs, and other fomites. The commonest complications are urethritis, proctitis, and cervicitis. Such epidemics are frequently exceedingly difficult to control and constitute a serious problem in many institutions such as children's wards in hospitals.^{9, 64}

Gonorrheal ophthalmia of the newborn is a well-known consequence of maternal infection; infection does not occur in utero but during passage through the birth canal. Although exact information is not obtainable, it is estimated that 10 per cent of all cases of blindness are traceable to this source and that in the United States there are perhaps 12,000 children blind from this cause. Infection may be prevented by the prophylactic instillation of silver salts such as silver nitrate. Some of the antibiotics, ³⁹ especially penicillin, are equally effective and may be given by the intramuscular route. ¹²

Except in the case of vulvovaginitis in children, gonorrhea is spread by direct contact, usually sexual. Once infected, an individual may remain infective for a long time, and gonococci may persist in the genitourinary secretions for years after apparently

complete recovery, and even though they may not be found by bacteriological examination the infection may be transmitted. Gonorrhea persists, then, in the human population in a smoldering endemic form and, as consequence of the nature of its transmission, widespread epidemics in the usual sense do not occur.⁷⁵

Bacteriological diagnosis of gonococcal infection.^{55, 73} A diagnosis of gonorrhea is established with certainty only by isolation and identification of the causative microorganism. The latter assumes significance in view of observations such as those of Johnston,³⁰ who found that 35 of 43 cultures were Neisseria other than the gonococcus, and the incidence of 1.5 to 3.4 per cent of Neisseria other than gonococcus reported by Wilkinson.⁷² In fact, nongonococcal urethritis may be more prevalent under certain conditions than gonococcal infection, the condition being associated with Mycoplasma.

While it has been said to be "primitive" by some workers, the demonstration of intracellular gram-negative diplococci in direct smears constitutes a presumptive, but not substantiated, diagnosis of gonorrhea. The validity of such diagnosis is enhanced by the application of fluorescent antibody staining to such smears.^{34, 46, 71} Diagnosis on the basis of stained smears is less reliable in the female than in the male, as is culture also.

It is generally agreed that culture of the gonococcus gives a higher proportion of positive results than direct smear examination alone, and cultured gonococci may be identified. The question of survival of this relatively delicate bacterium in transport of specimens is of some importance. Stuart's transport medium⁶³ is considered to be by far the most satisfactory. For culture an infusion chocolate agar, developed by McLeod, or minor modifications of it such as the plasma hemoglobin modification studied by Thayer, Schubert, and Bucca⁶⁶ is a medium of choice, and is inoculated directly with the specimen (or sediment if it is urine or spinal fluid). The culture must be incubated in 10 per cent CO₂; this atmosphere may be satisfactorily approximated by putting the plates in a jar together with a lighted candle and sealing or by the inclusion of a handful of moistened fresh oats in a sealed container with the cultures. Or carbon dioxide may be evolved from H₂SO₄ and an excess of bicarbonate, the amount of the former being determined by the volume of the container to a v/v concentration of 8 to 10 per cent. The oxidase test, carried out preferably by spraying the plates with the reagent from an atomizer or by pouring it on and off quickly, serves to differentiate the oxidase-positive colonies and, if picked immediately, they may be subcultured. Identification is based upon sugar fermentations in serum broth or serum agar containing an indicator. The fluorescent antibody staining technique may be applied to smears of pure cultures so isolated, as well as to direct smears as indicated above. 19

Chemotherapy. As described above, the occurrence of resistance to sulfonamides and antibiotics markedly affects successful chemotherapy. Disregarding such resistance, the gonococci are sensitive to sulfonamides, usually sulfadiazine, and to the antibiotics penicillin, erythromycin, tetracyclines, chloramphenicol, carbomycin, streptomycin, neomycin, and bactracin in that order, on the basis of activity per unit weight. Since streptomycin, which occurs far down on the list, is effective often in a single dose, there is a variety of available chemotherapeutic agents.

Pathogenicity for lower animals. The gonococcus is nonpathogenic for lower animals, aside from the toxicity of the cell substance as noted above, and gonorrhea has never been reproduced in experimental animals, including anthropoid apes. An experimental infection of the anterior chamber of the rabbit's eye has been described by Miller and his co-workers^{15, 44} in which the gonococci multiply and invade intraocular tissues, especially the ciliary body and lens, giving rise to a chronic infection in approximately one-third of the animals. This infection has been made use of in the study of the efficacy of chemotherapeutic agents.

Immunity. Little if any immunity to the gonococcus is acquired as a result of infection, and second and third infections may be superimposed upon the first, i.e., acute upon old chronic infections. As might be expected, then, the therapeutic use of vaccines and various types of antiserums is without effect. The significance of the observed extensive phagocytosis of gonococci by polymorphonuclear leucocytes is uncertain

Some degree of immunological response is evident, however. Complement-fixing antibodies are usually present, and patients may give a marked skin reaction to suspensions of killed gonococci. A number of attempts have been made to utilize these responses in the immunological diagnosis of gonorrhea. The complement-fixation test has shown some promise but is not generally used. The skin reaction is apparently too

variable to have practical value. It has also been observed that the discharges from gonorrheal inflammation give a precipitin reaction with antigonococcus serum, but this flocculation reaction has as yet no diagnostic value.

The Meningococcus

Inflammation of the meninges or investing membranes (pia-arachnoid) of the brain and spinal cord may be provoked by a variety of microorganisms and may occur either as a primary affection or secondarily in the train of an infection originally begun elsewhere. One form of meningitis, characterized especially by epidemic spread and usually designated as epidemic cerebrospinal meningitis, spotted fever, or cerebrospinal fever, is caused by a specific microorganism commonly known as the meningococcus.

This bacterium was described by Marchiafava and Celli in the meningeal exudate as early as 1884, but the first important work upon it was that of Weichselbaum, who, in 1887, obtained it in pure culture and described it in detail as the characteristic micrococcus found in six cases of acute cerebrospinal meningitis. Confirmation was supplied by the work of Jäger in spite of some faulty observation.

The meningococcus has been designated by a variety of names, including *Micrococ*-

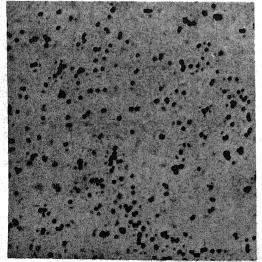

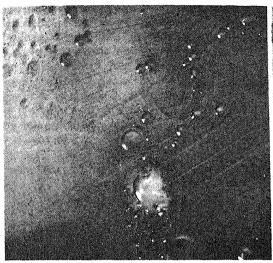

Figure 95. Meningococcus, pure culture. Note the typical diplococcus arrangement. Fuchsin; × 1050.

cus meningitidis, M. intracellularis meningitidis, Neisseria intracellularis, and, according to Bergey, N. meningitidis. Although Neisseria is generally accepted, common usage is divded between N. intracellularis and N. meningitidis.

Morphology and staining. In film preparations of the meningeal exudate the meningococcus is very like the gonococcus and occurs in pairs or tetrads both within the leucocytes and free. The diplococci are flattened toward one another like gonococci. and there is considerable variability in the size of different cells in the same smear. In cultures the meningococcus averages a little less than 1 μ in diameter and appears, as a rule, in pairs; short chains are seen more rarely. The variability in size observed in meningeal exudate may also be seen in cultures, particularly in those more than 24 hours old. Involution forms are common. and it is not unlikely that the larger cells are degenerative. Capsules are usually not apparent but become swollen in the presence of specific immune serum—the Quellung reaction. The meningococcus is nonmotile and does not form spores.

Meningococcus colonies in blood agar are moist, elevated, and smooth, and have a bluish gray tinge. They do not produce green discoloration or hemolysis and may be readily differentiated from the hemolytic and viridans streptococci and the pneumococcus. The colonies are not so white and opaque as those of the staphylococci.

The meningococcus stains readily with the usual aniline dyes and, like the gonococcus, is gram-negative. The involution forms found in cultures tend to stain unevenly, but even young cells may show the presence of metachromatic granules when stained by Löffler's alkaline methylene blue and other stains, and to a greater extent than the gonococcus. No sure distinction between the meningococcus and the gonococcus can be made on morphological grounds, and the identification of gonococci in gonococcal meningitis

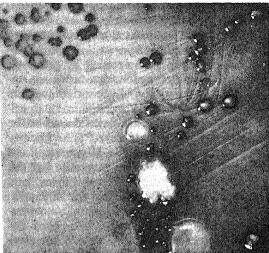

Figure 96. The oxidase test for the identification of meningococcus colonies. Mixed culture on blood agar. Left, colonies of meningococci and contaminants before the application of tetramethyl-p-phenylenediamine solution. Right, the same colonies after the application of the reagent. Note that the meningococcus colonies show the development of color first about the edges and there is slight discoloration of the medium. × 5.

is dependent upon culture and differential fermentations.

Physiology. Strains of meningococci vary considerably in the ease with which they may be cultivated; some strains will grow, although sparsely, on nutrient and infusion mediums but, in general, rich mediums containing serum or whole blood are required. Infusion base chocolate agar and blood agar are the most useful mediums. The nutritive requirements of meningococcus are similar to those of gonococcus, but some strains do not seem to require added cystine. Stock strains have been grown on synthetic mediums containing glutamic acid and cystine, or glutamic acid and lactate or glucose, and occasional freshly isolated strains will grow on these mediums.24,59

In isolating the meningococcus it is essential that the culture medium be warm when inoculated and kept warm until finally placed in the incubator. Growth is favored, especially in primary isolation, by incubation in an atmosphere containing 10 per cent carbon dioxide. The meningococcus will grow over a temperature range of 25° to 42° C., with an optimum at 37° C. Although sparse growth will occur under anaerobic conditions, the meningococcus is, for all practical purposes, an aerobe.

Continued cultivation on laboratory mediums results in more luxuriant growth, and the bacteria presumably become less nutritionally fastidious. Meningococcus cultures are difficult to keep, however, and tend to die out in stock culture. In most mediums these bacteria die within a few days if not transferred, but vitality may be preserved for several weeks in stab cultures in starch agar (1 per cent cornstarch in nutrient agar) and are best kept in the incubator.

The relatively early appearance of involution forms in meningococcus cultures as well as their limited viability when not transplanted is, perhaps, attributable to their formation of an active autolysin, and in saline suspension in the incubator autolysis may take place within a few hours. The autolysin is heat-labile, being destroyed at 65° C. in 30 minutes, and suspensions prepared for agglutination studies should be inactivated in this way.

The meningococcus, like the gonococcus, is a delicate microorganism and not highly resistant to deleterious influences. It is killed in a short time by drying and by exposure to dilute disinfectants. It is particularly sensitive to heat and cold and, unlike many bacteria, dies out within a few days at 0° C.

The meningococcus is not an active fermenter. Considerable quantities of acid, presumably lactic for the most part, are formed from glucose and maltose. The fermentation of maltose serves to distinguish the meningococcus from the gonococcus.

Neither is this bacterium actively proteolytic, for coagulated serum is not liquefied.

Toxins. Meningococcal meningitis in man and that reproduced in experimental animals are usually accompanied by profound toxemia. The meningococcus, however, appears to form no soluble toxin, though its cell substance is toxic to experimental animals and the toxin has been found to be lipopolysaccharide in nature.⁴² The toxicity is heat-stable (100° C. for 30 minutes) and the rate of its destruction suggests that the endotoxin consists of two substances, one much more thermostable than the other.

Variation. Rough and smooth colony types of the meningococcus have been described. Recently isolated strains are generally smooth while old stock cultures are rough. Mucoid colonies are observed. The change from smooth to rough is associated with a partial loss of immunological type specificity.

Classification. The meningococci are closely related to the gonococci, not only morphologically and physiologically but immunologically in that certain antigenic substances appear to be held in common as indicated previously.⁷⁸

The meningococci are not antigenically homogeneous, and occur as several serotypes, demonstrable by the agglutination and Quellung reactions, 45 which are determined by polysaccharide haptenes except one, the P substance, which is a toxic protein. The polysaccharides of type I (type A)³²

and type C (type $II\alpha$)^{69, 70} have been prepared in purified form, and the latter has been found to contain sialic acid and hexosamine. The relationship of the P substance to the endotoxins is not known. Differentiable types have been described by a number of workers since 1914, using different systems of notation. This has resulted in some confusion, and an internationally acceptable recommendation in which the serotypes are designated types A, B, C, and D has been agreed upon.⁵ The various systems of nomenclature are illustrated in the accompanying table.

While the routine typing of meningococci is probably not worth while, typing in connection with epidemiological studies, *i.e.*, the distribution of types occurring in healthy carriers as well as in cases of the disease, has been valuable.

Pathogenicity for man.³⁷ The resistance of man to meningococcal infection is relatively high, and the incidence of healthy carriers is invariably considerably higher than that of cases of the disease. It is probable that predisposing factors play a large part in determing whether or not infection will occur; insufficient clothing, inadequate ventilation, exposure to inclement weather, and fatigue very likely contribute in large measure to increasing susceptibility.

The meningococcus is initially present in the nasopharynx and from there gains access to the central nervous system. The route by which this occurs is uncertain; it is thought

[‡]The relation of this type to the others is unknown.

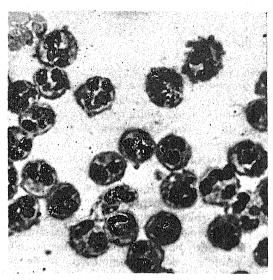

Figure 97. Meningococci in spinal fluid, showing phagocytosis of the microorganisms. Gram stain; \times 1050.

by some that the bacteria follow the perineural spaces of the olfactory nerves or set up a preliminary sinusitis and reach the brain either via the lymphatics or by direct extension through the bone. Others believe the meningococci reach the central nervous system via the blood stream through a preliminary bacteremia. While there is no definitive evidence concerning the means by which meningococci reach the central nervous system from the nasopharynx, the evidence appears to favor the hematogenous route. Occasionally the infection in the nasopharynx may extend into adjacent areas. giving rise to conjunctivitis, pneumonia, or other infections.

In the healthy carrier the infection remains confined to the nasopharynx and in this case is short-lived there and produces few or no symptoms. When the blood stream is invaded early in the disease, hemorrhages usually occur in the skin and petechiae appear, especially on the wrists and ankles, or on any mucous or serous surfaces. These are apparent in 24 hours after invasion and fade in a few days. The rash is quite different from other purpuric rashes: the spots take geometrical shapes and are highly irregular in size. Meningococci may be observed in smears of material taken from these lesions. Other symptoms include sudden onset, chills, fever, and meningeal symptoms such as headache and drowsiness. Pain in the arms and legs is common. The invasion of the blood stream may take the form of a fulminating meningococcemia (the Waterhouse-Friderichsen syndrome) adrenal with apoplexy as the immediate case of death and massive bilateral hemorrhage of the adrenals as the outstanding pathology. 29, 38, 49 This form of meningococcal disease is uncommon -little more than 200 cases have been reported-and occurs much more frequently in infants than in adults. Its sudden and violent character with rapid fatal termination has led to deaths due to this cause being classified as suspicious. The bacteremia may also take a more chronic form, and give rise to a purulent synovitis or meningococcal arthritis.7, 11

Upon reaching the central nervous system. the meningococcus sets up a suppurative lesion of the meninges which involves the surface of the spinal cord together with the base and cortex of the brain. The spinal cord lesions are of two main types during the acute phase of the disease: one is an acute transverse myelitis, and the other a poliomyelitic type. Later there is a diffuse arachnoiditis that constricts the cord and interferes with its blood supply and may result in extensive intramedullary changes. The microorganisms are invariably present in the spinal fluid, which may vary from a slight to a heavy turbidity. The bacteria are found, sometimes in great numbers, both free and within the leucocytes in smears of spinal fluid. The case fatality is variable, but in any case high, ranging from 35 to 80 per cent, and has been reduced to 16 per cent by improved methods of treatment, including chemotherapy.

There is some divergency of opinion regarding the nature and extent of sequelae to meningococcal meningitis, but these appear to include deafness, which is the most common; blindness; and pain and weakness of the neck, arms and legs. In a representative series of cases, for instance, 7 to 8 per cent of the patients showed sequelae persisting for nine to 30 months after recovery.

Epidemiology. 18, 21, 28, 79 Like most of the respiratory infections, meningococcal meningitis is disseminated by direct contact and droplet infection through the secretions of the mouth, nose, and throat. Infection is spread by patients and convalescents to a limited extent, but healthy carriers of meningococci are of primary importance. 52, 53 Some persons are temporary carriers, while

others are chronic, discharging meningococci more or less continously or in a snoradic fashion. Of a group of 10 carriers, half were of the chronic type, carrying what was apparently the same strain of microorganism for over two years. Weekly examination might be negative for a period, in one case as long as four and one-half months, and then the same type of meningococcus would appear. In a continuous survey⁴³ over a 17 month period of hospital staff and emplovees, the peak in carrier rate of 17 per cent was reached in April and May. Of 90 carrier strains isolated, 20 did not fall into the recognized types, and 70 were typable. Of the latter group, 16 were type I, 26 type II. and seven type $II\alpha$. Other studies of carriers have yielded similar results.61 Spouses of carriers were only occasionally carriers and then of a different type of meningococcus, suggesting a limited infectivity of the carrier strains.

The carrier rate is much higher than the incidence of the disease, and the theory that the second is a function of the first has been

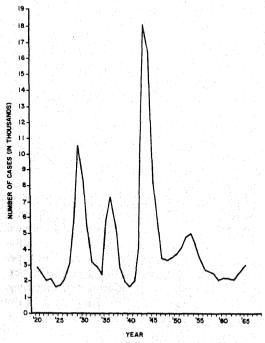

Figure 98. The prevalence of meningococcal infections in the United States during the period 1920–1965 as indicated by the number of cases reported. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

an intriguing one. Studies carried out during World War I suggested that there is a direct connection between the two, and that when the carrier rate exceeds 20 to 30 per cent. cases begin to appear. This relatively precise correspondence has not been substantiated. and the extensive studies of Aycock and Mueller¹ carried on during World War II showed that, while in general the prevalence of meningitis may be attributed to the prevailing type I carrier rate, variations in the incidence of disease between winter and summer, between the military and civilian populations, and between raw recruits and seasoned troops, were not associated with corresponding variations in the carrier rate.

Epidemics of meningococcal meningitis are prone to occur in military populations. and epidemic cerebrospinal fever was, with influenza, one of the most important diseases among the troops in the First World War. The influence of predisposing factors causing an increased susceptibility is especially marked under conditions of military life: fatigue, exposure to inclement weather. and similar factors very likely play a part in reducing the normal resistance of the raw recruit. This general reduced resistance, coupled with the opportunities for the dissemination of the microorganisms provided by the close communal existence in barracks, undoubtedly is an important factor in the genesis of these epidemics. Outbreaks in the civilian population differ in that children (over three months old) and adolescents are generally attacked; susceptibility appears to be greatest in children under 10 years of age, distinctly less in adolescents, and remains at a low level thereafter.

Whether occurring in civilian or military populations, epidemics of meningococcal meningitis have a number of distinctive characteristics. The relatively high carrier rate that may prevail, coupled with the low morbidity, estimated at 0.01 to 0.3 per cent of the exposed population, is an expression of a high degree of normal resistance, while the high case fatality rate indicates the serious course of the infection once established. The relative insusceptibility of the general population also results in the spotty character of the spread of the disease; some groups escape which are closely associated with the focus of infection, while in others, apparently remote, outbreaks occur. Direct transmission from case to case is not commonly observed. Usually carriers constitute

the link between cases. Further, epidemics frequently consist of a series of recurring outbreaks rather than the well-marked single epidemic wave often observed to occur in other diseases. In this country during the past five decades meningococcal meningitis has occurred in epidemic waves at six to 12 year intervals. Since 1925 there have been three major epidemics, centering in the years 1929, 1935, and 1943. Following 1943, there was a steady decrease in the numbers of cases and deaths until 1951. when the occurrence of a slightly greater number of cases of meningococcal infection suggested the possibility that another period of increased incidence might be developing. The incidence did, in fact, rise in the United States to a peak of 5077 cases in 1953 but subsequently declined to 2150 cases in 1962. Subsequently the number of reported cases increased to 2470 in 1963, 2825 in 1964, 3040 in 1965, and, provisionally, 3373 in 1966.

The seasonal incidence is marked in temperate climates. Males are more frequently attacked than females, although this may be an expression of risk rather than sex differences in resistance. Racial differences in susceptibility are indicated by military experience in which the morbidity and mortality rates of the colored troops were twice those of the white.

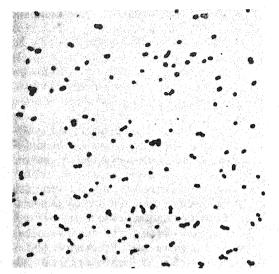

Chemotherapy. the chemothera-Of peutic drugs presently available, the sulfonamides, especially sulfadiazine, remain the drugs of choice. The meningococcus resembles the gonococcus in its in vitro sensitivity to the antibiotics, but these generally diffuse poorly and do not readily enter the central nervous system; penicillin may be given by the intrathecal route but appears to offer no advantage over the sulfonamides. Under special circumstances that warrant its use, i.e., the protection of recruits in the armed services, sulfadiazine is an effective prophylactic also, reducing both the carrier state and the incidence of the disease. With the continued use of sulfonamides for mass prophylaxis, the proportion of resistant strains of Group B has increased, though apparently this has not been true of Group A strains. 17

Bacteriological diagnosis of meningococcal infection. The meningococcus is present in considerable numbers in the spinal fluid in meningitis, and the finding of the characteristic gram-negative intracellular diplo-

cocci in stained smears of the sediment from centrifuged spinal fluid is sufficient to establish a provisional diagnosis. It may be cultured by the direct inoculation of spinal fluid sediment or nasopharyngeal swabs (in the detection of carriers) on infusion base chocolate agar or blood agar. Blood culture is useful early in the disease and in those cases which do not show meningeal symptoms. In asymptomatic carriers meningococci are found in the nasopharynx, and the specimen is taken from this area by swab.60 In any case it is important that the specimen not be allowed to cool below body temperature before inoculation of the warm medium. Like the gonococcus, the meningococcus is oxidase-positive and the oxidase test is especially useful for nasopharyngeal cultures. The isolated meningococci may be identified by fermentation tests and agglutination with polyvalent antiserum. Meningococci may be typed by agglutination, and in recent years the capsular swelling or Quellung reaction, described in the typing of pneumococci, has been used. Chicken antiserum is regarded as superior to rabbit antiserum by many workers. Typing is sometimes desirable in that a rise in the proportionate incidence of Group A usually precedes an epidemic of meningococcal meningitis, and dangerous carriers may be distinguished from relatively ones.4

Pathogenicity for lower animals. usual experimental animals are relatively resistant to the meningococcus upon intraperitoneal or intravenous inoculation. White mice are more susceptible than most other animals, and the injection of sufficient quantities of meningococci will result in death. Rabbits react similarly. Enormous numbers of bacteria must be injected and there is some question as to whether an actual infection is set up; killed meningococci are as effective as the living cells, and it is likely that the observed result is essentially a toxemia. The virulence of meningococcus for the mouse may be greatly increased by suspending the inoculum in mucin, but, as in other instances where it is necessary to use mucin, the relation of the artificial infection to the naturally occurring one is questionable.

Flexner was able to infect rhesus monkeys by the intraspinal inoculation of large amounts of meningococcus cultures, and the disease appeared to be more acute than

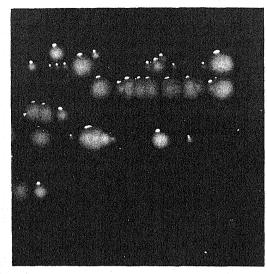

Figure 99. Neisseria catarrhalis. Left, smear from a pure culture. Note the diplococci and elongated forms which have not yet divided. Fuchsin; × 1050. Right, 24-hour culture on blood agar. × 5.

in man. Branham and her colleagues have been able to reproduce meningococcal meningitis in rabbits and in guinea pigs by the intracisternal injection of virulent meningococci. As in man, the experimental disease is both a local meningeal involvement with purulent meningitis and general toxemia. According to Branham it is easier to produce meningitis in guinea pigs than in rabbits. Similarly, a fatal meningoencephalitis may be produced in mice by intracerebral inoculation, though not by other routes. It is of interest to note that the developing chick embryo may be infected with meningococci; the 12-day embryos develop septicemia and hemorrhagic lesions simulating fulminating meningococcus septicemia in man.

Immunity. Infection with the meningococcus leads to the development of demonstrable antibodies, and patient's serum may agglutinate to a titer of 1:50. The development of agglutinins is irregular, or possibly appears so because of the antigenic instability of meningococci, and cannot be depended upon for diagnosis. Complement-fixing antibodies are produced also but too late in the disease (eight to 14 days) to be of diagnostic utility.

The injection of large number of meningococci into horses induces the formation of agglutinins, opsonins, and amboceptors. Antiserum is a reasonably effective therapeutic agent, and reduces the case fatality rate by about half, but is no longer used now that effective chemotherapeutic drugs are available.

Prophylactic vaccination with suspensions of meningococci has been attempted by a number of workers, but the procedure is difficult to evaluate. In general, there appears to be no consistent and unequivocal evidence of a significant degree of protection conferred by active immunization procedures.

Other Gram-negative Diplococci

In addition to the gonococcus and the meningococcus, two other species of non-pigmented gram-negative diplococci are generally recognized.

Neisseria catarrhalis is found commonly in the nasopharynx of healthy individuals as well as of persons suffering from colds and other respiratory infections. The cells as a rule are somewhat smaller than those of the meningococcus. Growth occurs on ordinary nutrient agar much more readily than in the meningococcus, and the colonies are generally thicker and more opaque. Dextrose and other sugars are not fer-

mented. Different strains vary in their pathogenicity for animals, but many strains are fully as pathogenic as meningococci for white mice. In man they appear at times to produce catarrhal inflammation, and sometimes pneumonia and meningitis have been reported. This was relatively common during the 1918 influenza epidemic in some localities.

Neisseria sicca is a small gram-negative coccus found on the mucous membranes of the respiratory tract. It grows at room temperature as well as at 37° C., forms white, firm, dry, adherent colonies, and ferments sucrose, lactose, and maltose. Although not ordinarily regarded as pathogenic, it has been found as apparently the causal agent in a case of kidney infection and has been found in the blood stream of patients ill with clinical endocarditis. This species as well as certain of the pigmented forms is found in an appreciable portion of cases of nongonococcal urethritis,30 but its pathogenic potentialities under these circumstances are not completely clear.

The pigmented forms. Gram-negative diplococci which form a pale greenish yellow pigment often best observed by transmitted light may be found in the upper respiratory tract of man. Although generally considered to be nonpathogenic, they are occasionally found in disease; for example N. perflava and N. flava have been found in meningitis^{36, 62} and endocarditis.⁴⁰ These pigmented forms are differentiated from one another on the basis of fermentations.

The anaerobic species. The obligate anaerobic gram-negative cocci are smaller than Neisseria, 0.3 to 0.4 μ in diameter, and occur in masses and short chains as well as in pairs. These forms appear to be nonpathogenic but occur as parasites in the mouth and respiratory tract and in the intestinal and urogenital tracts as well. They are placed in a separate genus, Veillonella, and divided into two main groups on the basis of gas production in culture mediums. The gas-forming group includes V. parvula, V. alkalescens, and V. discoides, and the nongas-forming group V. reniformis, V. orbiculus, and V. vulvovaginitidis.

Chapter Twenty

THE ENTERIC BACILLI

The Coliform Bacteria, Friedländer's Bacillus (Pneumobacillus), and Proteus

The gram-negative, nonspore-forming bacilli make up a large group of bacteria which includes intestinal commensals such as the colon bacilli and Proteus; the enteric pathogens such as the typhoid, paratyphoid, and dysentery bacilli; certain saprophytic forms and plant pathogens; and, as more distant relatives, the hemophilic bacteria (Hemophilus); the so-called hemorrhagic septicemia group (Pasteurella); and the causative microorganisms of undulant fever (Brucella).

The largest of these groups, and the subject of this and immediately following chapters, is that of the enteric bacilli, or Enterobacteriaceae. These bacteria are found in the intestinal tract of man and other warm-blooded animals, as commensals of limited pathogenic potentialities associated with diarrheal disease, or, and much less commonly, in infections of the tissues. There are other gram-negative bacilli which are more or less related to the enteric bacilli, but are differentiable from them.

Those grouped in the genus Serratia²⁰ are formally a part of the Enterobacteriaceae by virtue of cultural similarities, but are for the most part free-living saprophytes. Occasionally they are found in association with, and possibly causal relation to, pathological processes.^{26, 34} The most familar of these is the red pigmented Serratia marcescens. The pigment is not apparent in cultures incubated at 37° C., but the colonies are a bright-pink-red at lower temperatures. A majority of the Serratia are not pigmented, and in general these bacteria tend to be

somewhat less active biochemically than many of the enteric bacilli.

The gram-negative bacilli of the Aeromonas group^{24, 25} superficially resemble the enteric bacilli, and in fact certain strains, originally designated C27 paracolon bacilli, contain antigens also found in the Sonne dysentery bacilli. They also resemble Proteus in having polar flagella, and certain of them, like some strains of Proteus, are pathogenic for cold-blooded animals. A considerable number of species have been described from time to time, but these can be put into one or another of three species, viz., Aeromonas hydrophila, which produces red-leg disease of frogs; A. salmonicida, responsible for disease of trout and other fish; and A. shigelloides, antigenically related to dysentery bacilli. Aeromonas has rarely been found in association with disease of warm-blooded animals, including man, and is apparently nonpathogenic for them.

Still other bacteria are closely related to the enteric bacilli, in fact sometimes cannot be distinguished from them with certainty, but are set apart by differences in habitat. Such are Friedländer's bacillus, a common inhabitant of the upper respiratory tract and the causative agent of a small proportion of pneumonias, and the plant pathogens of the genus Erwinia which produce soft rots of vegetables. Similarly, the members of the genera Proteus and Pseudomonas occur as free-living saprophytes as well as intestinal commensals of occasional pathological significance.

CLASSIFICATION OF ENTERIC BACILLI

The differentiation and characterization of the enteric bacilli, or Enterobacteriaceae, is based upon a variety of biochemical and cultural reactions and upon antigenic structure; these bacteria are better known by these conventional criteria than any other group of microorganisms. When the more important of them, the typhoid and paratyphoid bacilli, the colon bacilli, and the dysentery bacilli, were first described and studied, it was not difficult to characterize them with reasonable precision, and they appeared to fall into genera and species in the limited sense in which these concepts seem to be applicable to microorganisms.

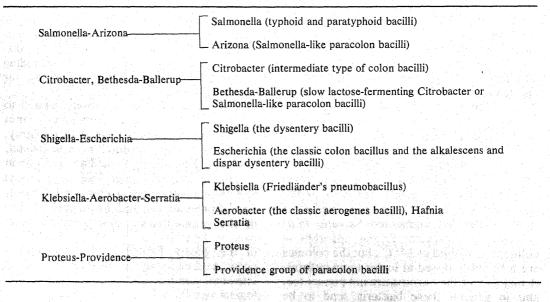

With increasing knowledge, it has become obvious that the enteric bacilli make up a continuous series of forms, showing almost every conceivable combination of differential characteristics. Combinations which have not yet been found in nature have, in some instances, been created in the laboratory by recombination and transduction, with demonstrable fertility groups crossing "genus" lines (Chap. Seven). Sharp distinctions are no longer possible, with different kinds of enteric bacilli merging imperceptibly into one another.

The inadequacy of the usual differential criteria as a basis for a formal classification or taxonomy, as distinct from a differential

key, is clearly evident in this group of bacteria. In fact, it is now becoming generally realized that subdivision of the family Enterobacteriaceae into the conventional tribes, species, and genera cannot be made on other than a genetic basis, which is as yet lacking, and that the species concept in the Linnaean sense is not applicable. At best, the enteric bacilli can be separated into groups, subgroups, and serotypes for purposes of practical expediency,⁴¹ and the construction of an elaborate and ambitious taxonomy of these microorganisms, and by inference possibly others also, is futile.

Nomenclature is another and distinct matter and some workable system is essential. 15, 51 Certain names, originally introduced as generic names, including Salmonella, Shigella, Escherichia, Klebsiella, and Serratia, have gained general acceptance, while others, especially certain species designations, have not. A practical basis of a nomenclature is usage, and therefore familiarity, rather than the priority demanded by the purist, for the latter has often resulted in the creation of new and unfamiliar genera and species which correspond neither with common international practice nor the great bulk of research literature, past and current. Here nomenclature in the controversial area of the enteric bacilli will be based on usage, and names are regarded as no more than useful handles without phylogenetic and taxonomic significance.

Groups and Subgroups of Enterobacteriaceae^{5, 21}

Physiological Differentiation of the Gram-Negative Bacilli*

*Prepared by Dr. R. S. Benham and Miss Isabelle Havens. †Differentiated immunologically.

Biochemical differentiation.^{9, 14} A useful primary differentiation can be made on the basis of the lactose fermentation which is roughly correlated with pathogenicity; the coliform bacteria ferment this sugar rapidly with the formation of acid and gas in 24 hours, while the bacteria of the other groups, essentially pathogens (Shigella, Salmonella), do not ferment it. The distinction is not absolute, since both the para-colon bacilli and certain of the dysentery bacilli are slow lactose fermenters, but is sufficiently marked to have considerable practical value.

Similarly, the dysentery bacilli, or Shigellas, divide into two groups on the basis of the fermentation of mannitol and are anaerogenic, that is to say, do not produce gas from fermented carbohydrates. While

the Salmonella group in general produces gaseous fermentations, the typhoid bacillus and Salmonella gallinarum are typically anaerogenic, and anaerogenic strains of other Salmonellas are occasionally met with. The general biochemical groups are idicated in the accompanying table of biochemical reactions.

The forms occurring in specimens from pathological processes in man are separable by systemic application of these biochemical characteristics, both as in the composition of mediums made selective by the inclusion of bile salts and differential by sugars and an indicator, and by specific biochemical tests. The practical application of these differential methods is illustrated in the accompanying scheme.

The Coliform Bacilli

The coliform bacilli were described by Escherich in 1886 as Bacterium coli commune and Bact. lactis aerogenes. It was soon evident that the former occurs as two fermentative types, Bact. coli communior, which ferments sucrose, and Bact. coli communis (or commune), which does not. Still another type, Bact. coli anaerogenes, ferments sugars without the production of gas. The type characterized by a ready mutation with respect to β -galactosidase, *Bact*. coli mutabile, has been discussed elsewhere (Chap. Seven). The generic names Escherichia, Aerobacter, etc. (see below), are now generally used. The microorganism described by Friedländer in 1883 as a causative agent of pneumonia, and known as Friedländer's bacillus or pneumobacillus, is closely related to the coliform bacilli. In addition to these, coliform bacilli characterized by a delayed or late (five to eight days) fermentation of lactose long occupied an anomalous position and were eventually called paracolon bacilli.

These forms are widely distributed and ubiquitous in the sense that they are universally found in the intestinal tract of man and many of the higher animals. Some varieties appear to occur free in nature, but it is probable that these represent contamination, although possibly distant, and these bacteria are primarily parasites of animals.

Morphology and staining. The coliform bacilli exhibit considerable variation in their

morphology. The usual dimensions observed in stained preparations from cultures upon nutrient agar or gelatin range from 2 μ to 4 μ in length and from 0.4 μ to 0.7 μ in breadth. Very short, oval and coccus-like forms are often found and usually predominate when the bacillus is observed directly in the normal animal. The bacilli are occasionally observed in pairs or short chains. Some varieties are encapsulated, particularly those found in pathological conditions. Motility is variable, although the most typical strains are motile by peritrichous flagella. Spores are not formed.

Colonies upon nutrient gelatin are more consistent and characteristic in appearance than those upon agar mediums. They are opaque to partially translucent, smooth, moist, and homogenous in consistency, with entire to undulating edge, and exhibit the maple-leaf appearance common to many of the enteric bacteria. Colonial morphology is somewhat variable upon nutrient agar. Typical colonies are opaque and grayish white, and there may be a tendency to become a light yellowish brown upon continued incubation. Pigmented varieties are occasionally observed. In certain differential mediums the colonies of coliform bacilli may assume other characteristics typical under the special circumstances. Upon Endo's medium, for example, the colonies are, of course, red, but in addition take on a curious metallic sheen that is highly characteristic when viewed by reflected light. Some varieties are β -hemolytic on blood agar; such hemolytic strains occur with much greater frequency in pathological processes than in the normal intestine.

Coliform bacilli stain readily with the ordinary aniline dyes and are gram-negative. Flagella may be demonstrated by special staining methods.

Physiology. The coliform bacilli are facultative anaerobes, growing equally well under aerobic or completely anaerobic conditions. They grow luxuriantly upon the ordinary nutrient mediums and may be cultivated in synthetic solutions containing an ammonium salt and an organic source of carbon such as glucose. Growth occurs over a temperature range of 10° to 46° C., there is good growth from 20° to 40° C., and the optimum is 37° C.

Milk is curdled with an acid reaction usually within 48 hours. Gelatin liquefaction, hydrogen sulfide production, and the formation of indol vary from one kind of coliform bacilli to another and have differential value.

Various sugars are actively fermented with the production of acid and gas. The ability to ferment a wide variety of sugars and other polyhydric alcohols is variable, and some of the fermentations are used for differentiating the various kinds of coliform bacilli. The greater part of the acid produced is lactic acid; smaller quantities of formic and acetic acids are formed, together with ethyl alcohol. Succinic acid is also found in variable but small amounts.

The coliform bacilli are ordinarily resistant to deleterious influences, being, as a rule, neither as resistant as staphylococci nor as susceptible as the more delicate bacteria. Most strains are killed by exposure to 60° C. for 30 minutes, but occasionally more resistant varieties are encountered. In common with the other gram-negative bacteria, they are considerably less susceptible to the bacteriostatic action of dyes than are the gram-positive microorganisms, and selective mediums containing dyes are commonly used in the primary isolation of the enteric bacteria. The ability of the coliform bacilli to grow in the presence of bile is likewise made use of in selective mediums (MacConkey's broth) in the bacteriological examination of water.

Variation. The existence of two colony types of coliform bacilli has long been known, the one the flat, maple-leaf form,

and the other a smaller, raised, round, moist type. The colon bacillus dissociates into rough and smooth colonial types, the S form giving rise to smooth, round, domed, shiny, translucent colonies, while the R colony type is characterized by an irregular dull surface, jagged outline, and opacity. It has been suggested that the R form is the more virulent.

Practically all kinds of microbial variation are not only known to occur among the coliform bacilli, but these have been by far the most commonly used bacteria for such experimental purposes. The K12 strain, for example, was used in the first recombination experiments, the *mutabile* strains provided one of the first and most thoroughly studied examples of mutation, and enzyme adaptation studies have been carried out to a considerable extent with these bacteria.

Toxins. As in the case of many other gram-negative bacteria, the cell substance is toxic to experimental animals upon parenteral inoculation. This endotoxin, presumably occurring as a lipid-polysaccharide-polypeptide complex, is separable as a toxic lipopolysaccharide, and is generally considered to be the prototype of bacterial endotoxins (Chap. Nine). A common antigen, present in very many if not all Enterobacteriaceae has O antigen properties, but apparently has little or no endotoxin activity. 43

A number of strains are hemolytic, as noted above. Two kinds of hemolysins are found. 46,56 One, designated α -hemolysin, is found in liquid culture supernatants, is separable from the cells by filtration, and is thermolabile and lethal for experimental animals. The other, β -hemolysin, is closely associated with the cells. Both lyse a wide variety of erythrocytes. These hemolysins do not appear to be associated with the pathogenesis of infections with hemolytic strains. 57

PHYSIOLOGICAL DIFFERENTIATION OF COLIFORM BACILLI

The coliform bacilli are separated into three groups on the basis of four biochemical reactions, and one of the groups further split using motility and gelatin liquefaction as criteria. The four biochemical reactions are the formation of indol from tryptophan, the methyl red test, the Voges-Proskauer

(V-P) reaction,^{7,59} and the ability to utilize citrate as a sole source of carbon.

The methyl red test is a determination of the pH of a dextrose broth culture after two to four days' incubation. The indicator is added to the incubated culture, and the test is said to be positive when the accumulated acidity is sufficient to turn the indicator red, and negative when the indicator remains yellow.

The Voges-Proskauer reaction is a qualitative test for the presence of acetyl-methylcarbinol among the later end products of glucose fermentation (Chap. Five). After two to four days' growth in glucose-peptone water medium, 5 ml. of a 10 per cent solution of KOH is added. On standing in the presence of alkali, the acetyl-methylcarbinol is oxidized to diacetyl which in turn reacts with some constituent of the peptone to give a pink color. When acetyl-methylcarbinol is produced, the bacterial strain is said to be V-P positive, and when it is not, V-P negative.

These four tests are fixed in order by the mnemonic "Imvic" or "IMViC" and are known as the imvic reactions. While there are 16 possible combinations of these reactions and, in fact, coliform strains giving each of these have been found, three groups are differentiated as indicated in the accompanying table. The classic colon bacillus, Escherichia (Bacterium) coli, is ++--, and the Aerobacter (Cloaca)-Klebsiella group is --++. Only one intermediate group, -+-+, is recognized; the bacteria of this group have been called E. freundii and are now designated Citrobacter freundii. Strains showing this combination of the imvic reactions are also called intermediate strains, or E. coli intermedium, which has no formal status. Other combinations have no formal name and designated "irregular." The relative distribution of these coliform types is shown in the accompanying table.

A number of other tests of biochemical activity are valuable in differentiating the coliforms from one another and from other enteric bacilli. These include the ability to grow in the presence of 1:13,000 KCN, the deamination of phenylalanine to phenylpyruvic acid, the utilization of sodium malonate, and decarboxylase activity with respect to arginine, lysine and ornithine. 18, 47 The usefulness of such tests varies from one group to another; for example, the utilization of malonate is useful in differentiation within the Klebsiella-Aerobacter-Serratia group, and the decarboxlyase reactions in the Aerobacter, Proteus, and Providence groups as well as in enteric bacilli other than coliforms. The utilization of the isomers of tartaric acid, used in the characterization

Percentage Distribution of Coliform Types*

Feces	87.9	5.2	6.8	0.1	3974

*As compiled from various authors. In many instances the strains studied were not isolated at random; the percentages are, therefore, weighted, and great significance cannot be attached to them.

of Salmonella species prior to the extensive development of serological typing, has been revived,⁴² and applied more broadly. The physiological character of the coliforms has been compiled and summarized.⁵⁰

The Aerobacter, or Cloaca, group is, as indicated above, broken down into two parts, Aerobacter (Cloaca) and Klebsiella. The former is widely known as Aerobacter aerogenes, corresponding to Escherich's Bact. lactis aerogenes. By definition, A. aerogenes is motile and fails to liquefy gelatin, while Klebsiella is nonmotile and liquefies gelatin slowly. The combination of properties represented by A. aerogenes is, in fact, extremely rare, and most strains which are motile also liquefy gelatin and are, again by definition, A. (Cloaca) cloacae, in the older literature Bact. cloacae. Thus the name A. aerogenes, widely used for coliform strains in genetic and physiological studies and in water bacteriology (Chap. Eleven), tends to drop out of existence. It has been suggested³⁶ that this situation be resolved by creation of a genus Enterobacter to include Aerobacter as two differentiable kinds, cloaceae and aerogenes, leaving Klebsiella to include the nonmotile forms.

In summary the coliform bacilli are separated into the following kinds: Escherichia coli, Citrobacter (Escherichia) freundii, the rare form Aerobacter aerogenes, Aerobacter (Cloaca) cloacae, and Klebsiella pneumoniae, the last Friedländer's bacillus.

THE IMMUNOLOGICAL RELATIONSHIPS OF THE COLIFORM BACILLI

The antigenic structure of the colon bacilli has been elucidated in great detail, and the coliforms may be identified as serotypes with a high degree of precision. 17, 29, 38 There appear to be three kinds of antigens present, viz.:

(1) Heat-stable O antigens, of which more than 100 have been found. Of these, 25 occur with sufficient frequency for diagnostic use with most strains of coliform bacteria.

(2) Somatic surface antigens, designated as "envelope" antigens or K antigens. These function as "blocking antigens" in that their presence interferes with agglutination with O antiserums. Three kinds of

K antigens have been described:

(a) Those which are designated L antigens are thermolabile, and the O agglutinability of bacterial suspensions is restored by boiling. L antiserums may be prepared by absorption of LO serums with the homologous O antigen, viz., boiled bacteria. The colonies of strains containing L antigens are somewhat more opaque than those which do not contain them. About 24 L antigens have been described.

(b) The component of the K antigen designated the A antigen is present in encapsulated coliform bacilli, is a specific polysaccharide, and bacteria containing it give a Quellung reaction in antiserum. It differs from the L antigen in that it is thermostable. So-called N variants lacking the antigen are found in translucent areas at the edge of the large, dense, and relatively opaque colony. About 20 A antigens have been found.

(c) An antigenic component of the K antigen complex, designated the B antigen, is thermolabile but differs from the L antigen in that the heated antigen can absorb antibody though heated suspensions will not agglutinate in monospecific B antiserum. The B antigen

appears to be relatively rare.

(3) The flagellar or H antigens of the coliform bacilli are often poorly developed. Some 22 components have been found, of which 20 are used for purposes of identification.

Kauffmann has developed a serological classification of coliform bacilli, largely based on the distribution of O, K, and H antigens. In general, about 80 per cent of strains having K antigens contain L antigens, and the other 20 per cent contain A antigen or B antigen. Strains containing K antigen appear in a general way to be the more toxic and more resistant to phagocytosis and the bactericidal action of antibody and are found more frequently in pathological material than in feces.

Some of the coliform bacteria are immunologically related to some of the other gram-negative bacilli, such as the plant pathogens, Friedländer's bacillus, Salmonella, Shigella,²³ and Pseudomonas,⁶⁸ while others appear to be related to certain of the pneumococcus types.

The interesting observation has been made⁵⁵ that while most of the colon bacilli harbored by a given individual may be immunologically identical, or nearly so, individuals show a continuous succession of types, each predominating for a few weeks or months and then being replaced by a fresh type, or serotypes may persist for extended periods. Such changes are apparently not associated with host antibody response.⁵² It was noted also that immunologically identical types were sometimes biochemically different.

Pathogenicity for man. The pathogenicity of the colon bacilli in their natural habitat. the intestinal tract, is ordinarily very slight. These bacteria are associated with institutional outbreaks of infant diarrhea, and a number of serotypes are found, and are probably causally related to the disease. 16, 19 Two were differentiated relatively early and have been given a number of designations. One of these has been called Bact, coli neapolitanum, E. coli D433, E. coli α-type, Bact. coli Bray or BGT, and E. Coli O Group 111. The other is E. coli β -type or E. coli O Group 55. These O serological groups, usually designated O55 and O111, are those arbitrarily numbered by Kauffmann, and provide precise identification. E. coli O55 is immunologically related to the pathogenic paracolon bacilli of the Arizona group, and E. coli O111 to the Salmonella antigen XXXV.40

A considerable number of other O serotypes have now been associated with diarrheal disease, including O26, O44, O86, O112, O119, O124, O125, O126, O127, and O128. Compilation of available data²⁸ has shown that the serotypes, more precisely defined by inclusion of additional antigens, most often associated with diarrheal disease in this country are: 055:B5:-;055:B5:H6; O55:B5;H7; O111:B4-; O111:B4:H12; and O127:B8:-. Such complete serotyping is necessary if accurate data are to be obtained.

These serotypes occur for the most part in man, and enteropathogenicity has been demonstrated in human volunteers. ⁶¹ Enteropathogenic strains also give the rabbit gut reaction, ^{63, 66} in which ligated loops of the lower small bowel are infected; this disease model was devised by De and his associates in connection with cholera and has been used extensively in the study of that disease (Chap. Twenty-three). It has been observed

KLEBSIELLA 487

too that positive reactions, manifested as accumulation of intralumenal fluid with marked distention of the loop, are also produced by killed enteropathogenic coliform strains.⁶²

The presence of these serotypes is not necessarily associated with diarrheal disease; *i.e.*, they are not invariably enteropathogenic. In one study⁵⁸ of children in the 0-2 age group, for example, the asymptomatic carrier rate was 5.6 per cent. Of those infected 41 per cent showed no symptoms, and the proportion increased with age.

The causative agents of infant diarrhea differ in various parts of the world and generally reflect economic and public health conditions. In backward countries with a high infant mortality rate due to diarrheal disease, the causative microorganisms are most commonly the Flexner and Shiga dysentery bacilli (Chap. Twenty-two), the common causes of adult dysentery. In advanced countries the dysentery bacilli, and to a considerable extent Salmonella, are less common causes of infant diarrhea, and are replaced by coliforms.⁵³ The picture in this country is similar to, for example, that observed in England⁶⁰ and France.⁴⁵

The laboratory diagnosis of diarrheal disease of coliform etiology has been systematized⁵⁴ and, as indicated above, involves detailed serotyping. A rapid presumptive identification of enteropathogenic coliforms in rectal swabs, using the fluorescent antibody technique, has been worked out in detail^{4, 64} and appears to be very promising.

Outside the intestinal tract, the colon bacilli have definite pathogenic potentialities. The urinary tract is probably the most fre-

quently invaded, and the majority of cases of cystitis are of coliform etiology. In such infections the bacteria are usually present in the urine in numbers of 100,000 or more per milliliter; 20,000 or less probably represents contamination. The colon bacilli may also play a part in the formation of gallstones; the bacillus is frequently found in the core of gallstones and, in culture, can precipitate cholesterol and other biliary constituents. The injection of colon bacilli into the healthy urinary bladder or gallbladder does not produce infection in experimental animals, but infection occurs if the bile duct or urethra is obstructed. Local infections such as abscesses, conjunctivitis, and the like, have been observed but are not common. E. coli septicemia is very rare but may occur as an agonal invasion in acute infective processes. A hemorrhagic septicemia caused by E. coli sometimes occurs in newborn infants and is known as Winckel's disease.

Pathogenicity for lower animals. E. coli is of low pathogenicity for laboratory animals. Two milliliters of a broth culture injected intraperitoneally will kill a guinea pig within a few days, and killed bacilli are very nearly as effective. Spontaneous infection of lower animals is not common. The diarrhea of young calves known as scours has been attributed to E. coli septicemia.³² The colon bacillus is also thought to be a factor in the causation of diarrhea of foals and young pigeons. Local infection may occur; in one series of 286 cases of bovine mastitis, 10 were apparently due to members of the colon-aerogenes group, of which three were typical E. coli.

Friedländer's Bacillus (Klebsiella pneumoniae)

The microorganism described by Friedländer as an etiological agent of pneumonia is, as indicated above, nonmotile and, as found in the respiratory tract, usually heavily encapsulated. Motile strains occur in such pneumonias, however, and strictly speaking they are not *Klebsiella pneumoniae*, but the distinction is not relevant to the disease produced. Occasional strains are pleomorphic in culture. Friedländer's bacillus is readily isolated from sputum from cases of

the pneumonia caused by it by culture on blood agar. The growth is heavy and viscous, and the colonies unusually large. For practical purposes, this kind of growth and demonstration of the gram-negative, thick, ovoid rods, often occurring in pairs, suffices for identification.

As indicated earlier, these bacteria are extremely closely related to the aerogenes type of coliform. Differentiation may be exceedingly difficult^{30, 49} if not practically

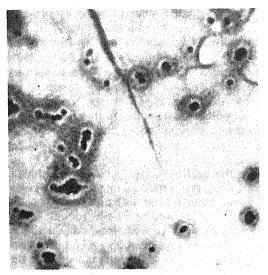

Figure 100. Klebsiella pneumoniae (Friedländer's bacillus) in pure culture on blood agar, showing capsules. Crystal violet; × 1200.

impossible at times, and is irrelevant to the bacteriological diagnosis of pneumonia. Detailed examination of strains allows differentiation within Klebsiella into K. pneumoniae, K. ozaenae and K. rhinoscleromatis, the last two being associated with a type of chronic upper respiratory tract infection, together with certain other types given species names. 6, 39

Immunological types. This group of bacteria, including both motile and non-motile forms, contains three kinds of antigens, designated O, A, and K, and analogous to those of *E. coli*. The bacteria are typed on the basis of the capsular antigen, and a total of 57 capsular types have been described. The Quellung reaction does not occur in specific antiserum, but a precipitin reaction takes place at the periphery of the capsule, making the margin highly refractile. There appears to be no variation in virulence associated with capsular type.

Pathogenicity. Microorganisms of this group are found associated with various kinds of upper respiratory disease in man, and in most instances are probably secondary invaders, as in the nasopharynx in persons having cronic sinusitis or chronic lung infections such as bronchiectasis.

Pneumonia due to Friedländer's bacillus makes up 0.5 to 4.0 per cent of all pneumonia, but the case fatality rate is high, 90 per cent or more in untreated cases. The microorganism has a greater tendency to

produce necrotic lesions than pneumococcus, and the infection contrasts with pneumococcal pneumonia in that while it is similar in its very early stages with a spreading zone of infected edema around an older area of dense exudate, as the infection progresses the alveolar walls become involved and disintegrate, and multiple areas of purulent exudate become necrotic. Thus the pathological response is necrosis of the lung parenchyma and subsequent healing with fibrosis, commonly accompanied by abscess formation, cavitation, or bronchiectasis. The sulfonamides and broadspectrum antibiotics, but not penicillin, are reasonably effective, and according to some workers are more effective in combination:

Probably antimicrobial treatment instituted very early would result in complete recovery, but the infected individual is usually not hospitalized until the second day, and another day is wasted with penicillin therapy. In the drug-arrested infection, the affected areas become a lesion consisting of one or more cavities lined with necrotic material connected to damaged bronchi, and chemotherapy transforms the acute, often fatal, condition to a subacute or chronic infection.

Despite chemotherapy the residual lung damage frequently requires surgical drainage and later pulmonary resection. During surgery there is some likelihood of a flare-up

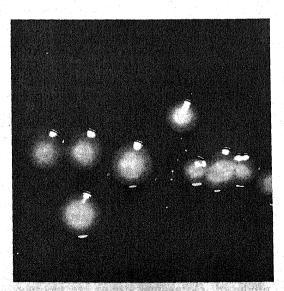

Figure 101. Colonies of Friedländer's bacillus on blood agar. Note the large size and mucoid appearance.

of infection in the contralateral lung due to persistence and drug resistance of the infecting microorganism.^{37, 69}

Klebsiella has also been associated from time to time with suppurative conditions in various parts of the body, such as liver abscess and meningitis, 65 and rarely has been found to invade the blood stream to produce septicemia. Infection may also occur spontaneously in lower animals, and these bacteria have been found to be the etiological agents of epidemic respiratory infection in mice, a paralytic disease of moose, and metritis of mares.

The Paracolon Bacilli

The term paracolon bacillus is applied to enteric bacilli similar to the colon-aerogenes group, but distinguished from it by a delayed (five to 21 days) fermentation of lactose. On the basis of the IMViC reactions, these slow lactose fermenters range from a typical coli type to a typical aerogenes type. Certain biochemical types of paracolon bacilli closely resemble the Salmonellas and, especially when the lactose fermentation is long delayed, may present a practical problem in reasonably rapid identification.

Study of the serological character of some of these forms, especially those that are found in apparent etiological relationship to enteric disease, has shown that they are related on the one hand to coliform bacilli and on the other to Salmonella, and some antigenic components are shared with certain of the dysentery bacilli. Still others are more closely related to Proteus. Their division into groups is more a matter of convenience for purposes of study than a recognition of sharply defined differences among them. A number of such groups are generally recognized;8 a rough approximation of their relationship to one another and to other enteric bacilli, arrived at only by disregard of some apparently minor resemblances, is shown in the accompanying diagram.

The Bethesda-Ballerup group. 31, 67 The paracolon bacilli in this group closely resemble the Salmonellas in the usual biochemical characteristics except that they ordinarily, but not invariably, ferment lactose and sucrose, and often salicin, on prolonged incubation. They were originally regarded as two separate types, one of which was described as Salmonella ballerup though it was immunologically related to the other Salmonella types only through its content of Vi antigen.

The first of the Bethesda group of para-

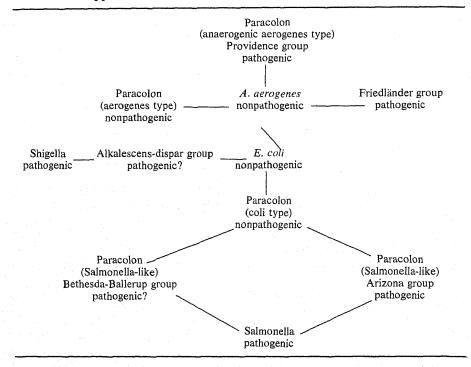

colon bacilli were originally isolated in Bethesda, Maryland, but subsequently they have been found widely scattered over the country. Many of the Ballerup strains are late lactose and/or sucrose fermenters and are now regarded as paracolons, and have been merged with the Bethesda group since the two are closely related antigenically. So far 32 O groups and 74 H antigens are recognized and occur in various combinations to give a multiplicity of serological types. These bacteria have been isolated with some frequency in association with enteric disease, and at least some strains are possible pathogens. They are often encountered in diagnostic work and are not rapidly separable from Salmonella by biochemical tests; pooled and polyvalent antiserums facilitate their recognition.

The Arizona group. 12, 22 These bacteria were first described as Salmonella found in reptiles and resemble the Salmonellas closely except that most strains ferment lactose within two weeks. They are closely related serologically to Salmonella; many of the O antigens are identical with those of Salmonella, and the H antigens are closely similar. These bacteria fall into 76 O groups, and 75 serological types have been described. It appears to be definitely established that this group of paracolon bacilli is regularly pathogenic, not only for coldblooded animals, but also for fowls and man, and in the last two produces infections as severe and fatal as do the Salmonellas.

The Providence group.¹³ This group is made up of paracolon bacilli of an aerogenes type (citrate-positive) that are anaerogenic, *i.e.*, produce little or no gas from glucose. They were originally described as the 29911 group but are now known as the Providence*

^{*}They were originally described and have been studied most intensively by Stuart and his co-workers at Brown University in Providence, Rhode Island,

Approximate Interrelationships of the Enteric Bacilli

group. They are closely related to Proteus, so much so that it has been suggested that they be considered as a species of Proteus, *Pr. inconstans*. They have been associated with institutional outbreaks of diarrhea

among infants and may be regarded as possible pathogens. Their serology is as yet incompletely worked out, and this has hampered their identification in association with enteric disease.

Proteus 13

These microorganisms were originally described by Hauser as an independent genus containing three species-Pr. vulgaris, Pr. mirabilis, and Pr. zenkeri. It is now generally agreed that the last is not closely related to the typical members of the group (it is gram-positive), and it is now placed in a separate genus as Kurthia zenkeri. As indicated earlier, Proteus is included under the Enterobacteriaceae and is related to but nevertheless distinct from the other enteric bacilli. It is found with some frequency in normal feces and often increases proportionately during or immediately after attacks of diarrheal disease caused by other organisms. It is one of the most common bacteria in soil and water containing decaying organic matter of animal origin and usually occurs in large numbers in sewage; it is perhaps to be identified with the "bacterium of putre-faction" or *Bact. termo* of early writers. Like the enteric pathogens it does not ferment lactose, and it resembles them in its growth on differential and selective mediums. It may be confused with Salmonella because of its motility and gas formation during carbohydrate fermentation, but is distinguished by its ability to hydrolyze urea.

Morphology and staining. In general, these bacteria appear as straight or slightly curved rods 1 to 2.5 μ in length and 0.4 to 0.6 μ in breadth, frequently in end-to-end pairs and short chains. Ovoid forms are common, however, and long, curved, filamentous cells predominate in actively

swarming cultures. Proteus is actively motile by peritrichous flagella and forms neither capsules nor spores.

The phenomenon of "swarming" exhibited by these bacilli is a consequence of their active motility. On the surface of agar mediums the colonies do not remain compact and discrete; the growth spreads rapidly over the entire surface available as a thin. scarcely visible bluish film. Microscopic observation shows that the bacilli break away from the edge of the growth and migrate or "swarm" over the surface of the medium, thus giving rise to the thin film of growth. This property is a source of considerable inconvenience in the isolation of bacteria other than Proteus from mixed cultures in which it is present; the inclusion of 0.01 per cent sodium azide inhibits the growth of this and other gram-negative bacilli but allows the growth of streptococci.

These bacilli stain readily with the usual aniline dyes and are gram-negative.

Physiology. The nutritive requirements of Proteus are simple, and the bacilli grow readily upon the ordinary laboratory mediums. They may be cultivated in synthetic solutions containing ammonium lactate, but nicotinic acid must be supplied. The optimum temperature for growth is 30° to 37° C., though good growth occurs at 20° C. These bacteria are facultative anaerobes, but anaerobic growth is generally very poor.

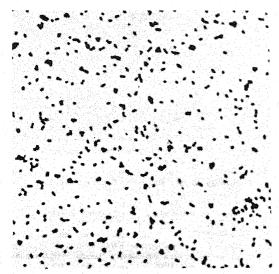

Figure 102. Proteus vulgaris. Smear from a pure culture. Note the coccobacillary form. The occasional occurrence of paired cells is a result of active multiplication. Fuchsin; × 1050.

Figure 103. Proteus vulgaris colony on blood agar. Note the swarming, exhibited as successive waves of growth. (Dack.)

Gelatin is liquefied more or less rapidly, often with a characteristic colony formation with radiating filaments which wander far off into the surrounding medium. The typical Proteus colonies are best formed when the gelatin is soft, as happens when it is kept at a temperature not far below the melting point or is made up with 5 instead of 10 per cent gelatin. Dextrose is fermented with actd and gas production; sucrose and maltose are fermented by some, but not by all, strains; lactose, raffinose, and mannitol are never fermented by the typical Pr. vulgaris. The Voges-Proskauer reaction is negative and the methyl red test positive. Nitrates are reduced. Milk is at first rendered slightly acid, then curdled with alkaline reaction (in about three days), and more or less slowly peptonized. While species of Proteus other than Pr. morgani are actively proteolytic, these bacteria apparently do not play an important part in the anaerobic decomposition of proteins or putrefaction as was once supposed. Under aerobic conditions proteolysis occurs rapidly, i.e., decay or nonputrefactive proteolysis.

At the present time the bacteria comprising the genus Proteus are classified entirely on a biochemical basis.²⁷ As noted above, the group is distinguished by its ability to hydrolyze urea. Four species are recognized: Pr. vulgaris, Pr. mirabilis, Pr. rettgeri, and Pr. morgani; the last is known in the earlier literature as Morgan's bacillus (see below). These are distinguished from one another on the basis of the fermentation of mannitol, maltose, and sucrose and the formation of indol.

AUDIONE

Antigenic structure. Proteus contains both H and O antigens when motile, and the nonmotile, nonswarming strains contain only O antigen. Three colonial types have been observed, and antigenic analysis of the O and H antigens has given 18 O groups in 44 strains, with recurring and crossing of H antigens and some suggestion of phase variation. The ureases of Pr. vulgaris, Pr. mirabilis, and Pr. rettgeri have been found to be serologically indistinguishable, but that of Pr. morgani is antigenically distinct. The ureases of the colonial distinct.

Certain Proteus strains are agglutinated by the serum of patients having typhus fever. These so-called X strains contain an antigen common to the typhus rickettsiae, and the agglutination of these bacilli (the Weil-Felix reaction) is of diagnostic value in typhus fever. In the Proteus strains the antigen is a part of the O antigen, and its specificity is determined by an alkali-stable carbohydrate haptene which is also found in *Rickettsia prowazeki*. The X strains frequently ferment maltose.

Pathogenicity. Proteus, both in mixed and pure cultures, has been found to be associated with a variety of pathological conditions. Infections of the eye and ear, pleuritis and peritonitis and suppurative abscesses in many parts of the body are among the many instances in which an etiological role is highly probable. As a producer of cystitis and pyelonephritis it ranks next to E. coli. In experimental infections of the mouse kidney, Proteus has been found to be considerably more virulent than Pseudomonas or Escherichia.33 There is evidence³ that Proteus urease is nephrotoxic. favoring the intracellular infection of the tubular epithelium and creating an alkalinity in the kidney which leads to necrosis of renal tubular epithelium with the precipitation of MgHPO4 with the formation of stones. Besides its independent pathogenicity, it is found commonly associated with other microorganisms in purulent war wounds and similar processes.

In certain affections of the digestive tract Proteus has been frequently held to be the responsible agent. In diarrheic stools, especially those of infants, it has often been found in large numbers and is regarded by many as a cause of infant diarrhea. The real relation of Proteus to intestinal infection is, however, still obscure. Certain foodpoisoning epidemics have been ascribed to Proteus.

Animal inoculation shows that a great range of virulence exists among the Proteus cultures that have been tested. Freshly isolated strains from pathological sources may produce definite lesions, including abscesses, enlargement of the spleen, and a diarrheic condition. The etiological agent of red-leg disease of frogs, ulcer disease of brook trout, and red sore of pike has been found to be a bacillus closely related to the Proteus group, and it has been classified as Pr. hydrophilus, 44, 48 and is not to be confused with Aeromonas species, which are also pathogenic for cold-blooded animals to produce similar diseases. The cell substance of these bacteria is toxic on parenteral injection and, as in the case of the enteric forms, the toxin appears to be a glucolipid. No difference in toxicity is apparent between strains of pathogenic and nonpathogenic origin.

This bacillus was Morgan's bacillus. isolated by Morgan in 1906 from the stools of infants suffering from summer diarrhea. Although it was first designated as Morgan's No. 1, the other varieties of Morgan's bacilli have long since faded out of general interest and recognition so that the name Morgan's bacillus is usually applied to Morgan's No. 1. It is closely related to the Proteus group, and it is classified as Pr. morgani. This bacillus appears to have played a part in a number of outbreaks of summer diarrhea of infants and has been isolated from paratyphoid-like fevers. It has been found to give rise to spontaneous epidemics of enteritis in mice. Injected intraperitoneally into mice, Morgan's bacillus produces a rapidly fatal infection.

Chapter Twenty-one

THE ENTERIC BACILLI

The Salmonella Group

The enteric bacilli comprising the large Salmonella group are all pathogenic to a greater or lesser degree and include the typhoid bacillus, the paratyphoid bacilli, and a wide variety of forms whose natural hosts are lower animals, especially rodents and birds.

The infectious nature of typhoid fever was apparent in 1856 to William Budd, who, on the basis of epidemiological evidence, suggested that the disease was transmitted by sewage-contaminated water and that the source of the infectious agent was human feces. The typhoid bacillus was found by Eberth in 1880 in the mesenteric glands and spleen of persons dying from typhoid fever and was cultured in 1884 by Gaffky.

The rodent pathogen, Salmonella enteritidis, was described in 1888 by Gärtner, who isolated it from infected beef responsible for an outbreak of gastroenteritis, and in the older literature this microorganism is known as Gärtner's bacillus.

For a good many years the kinds of microorganisms making up the "typhoid-paratyphoid group" were relatively few and confined largely to those differentiable by cultural reactions. With the development of the techniques of antigenic analysis and their application to these microorganisms in the 1920's, very many serologically differentiable types or kinds were, and continue to be, described until by now the Salmonella group is made up of many hundreds of differentiable types.^{29, 54}

Morphology and staining. These bacilli are gram-negative rods closely resembling and indistinguishable from the coliform bacteria. They stain readily with the usual dyes such as methylene blue and carbol-

fuchsin. No particular arrangement of the cells is apparent on microscopic examination. All species except *Sal. pullorum* and *Sal. gallinarum* are actively motile by means of peritrichous flagella. No capsules are apparent, and spores are not formed.

Physiology. The bacteria of this group have simple nutritional requirements, growing readily on the usual nutrient mediums. In synthetic mediums an ammonium salt and glucose, pyruvate, lactate, etc., are adequate sources of nitrogen and carbon. The great majority of strains do not require bacterial vitamins or amino acids, but some strains of the typhoid bacillus require added tryptophan. The optimum temperature is 37° C., but growth occurs at a reasonable rate at room temperature. They are facultative anaerobes, growing equally well under either aerobic or anaerobic conditions, and some species develop relatively strong reducing tendencies.

The group is characterized biochemically by failure to ferment lactose or salicin and inability to liquefy gelatin or produce indol. There are a very few exceptions to the two last; Sal. eastbourne and some strains of Sal. enteritidis and Sal. panama produce indol, and Sal. daressalaam liquefies gelatin. The evolution of gas commonly accompanies the fermentation of sugars, though anaerogenic strains of Sal. enteritidis, Sal. typhimurium, and Sal. paratyphi C have been reported. Sal. typhi, however, characteristically ferments sugars without the formation of gas.
